Osteotomy and Completion

- Lines for the osteotomy are placed on the maxillae (**TECH FIG 5A-C**).
- The osteotomy begins medially via the transconjunctival incision from the medial aspect of the infraorbital rim through the frontal process of the maxilla into the cranial aspect of the piriform aperture bilaterally, allowing avoidance of the medial canthal tendon and lacrimal apparatus (**TECH FIG 5D**).

TECH FIG 4 • A,B. Prefitting the maxillary devices onto the skull model prior to placement in the patient. **C.** Placement of the marker screws in relation to the osteotomy sites. **D.** Initial in situ fitting of the distraction device prior to the osteotomies. **E.** The device has been removed and the marker screws have been placed. The screws allow the appropriate placement of the proposed osteotomy location in

relation to the devices. Screw placement also allows easy and accurate placement of the devices after completion of the osteotomies.

- The osteotomy continues via the lid incision with an osteotome or ultrasonic scalpel posterior to the infraorbital rim, extending medial to lateral, to the level of the lateral aspect of the infraorbital foramen (**TECH FIG 5E**).
- A lateral canthal extension of the transconjunctival incision allows the osteotomy to proceed through the lateral buttress in a number of vectors:
 - A high Le Fort I pattern down to the pterygomaxillary fissure
 - Through the zygomatic arch–zygoma junction
 - Through the caudal 5 mm of the lateral orbital wall in patients with more significant lateral malar hypoplasia
- The pterygomaxillary disjunction proceeds via the vestibular incision.
- Elevation of the nasal floor along the piriform aperture facilitates placement of the Rowe disimpaction forceps to allow a controlled mobilization of the midface segment.
- Two options exist for distraction:
 - An external halo device can be applied with pin sites along the medial and lateral buttresses above the apical roots.
 - An internal maxillary distractor can be applied with footplates above and below the transverse or oblique osteotomy along the lateral buttress.
- Control of the midface pitch during distraction is achieved with Bollard plates, C-plates, or TADs attached to intermaxillary class III elastics to help prevent clockwise rotation during transport.

TECH FIG 5 • **A.** Outline of the quadrangular osteotomy on the maxilla on the intraoperative skull model. **B.** After the marker screws have been placed, the lines for the osteotomy are placed on the right maxilla. **C.** Lines for the osteotomy are then placed on the left maxilla. The osteotomy is outlined medial to the marker screw on the malar eminence and must capture some of the malar eminence before extending

onto the lateral buttress. **D.** Illustration of the medial and lateral osteotomies of the maxilla extending to the infraorbital rim. **E.** Osteotomy across the orbital floor with an osteotome using the transconjunctival incision.

PEARLS AND PITFALLS

General

- Distraction procedures do not require intraoperative occlusal fixation or postoperative maxillary mandibular wire closure. Therefore, oral intubation is appropriate for these procedures.
- An oral RAE tube can be placed and is easily positioned away from the operative field. If prolonged intubation is anticipated, a regular endotracheal tube provides better access for suction in the ICU and is preferred.
- If Le Fort II distraction with an internal maxillary device is planned for a patient with a cleft and midface deficiency, a quad-helix orthodontic expansion device is placed prior to the procedure. The device is not used for expansion but provides a more rigid appliance during late distraction, when vector forces tend to be directed to the midline.
- A 2.0-mm bridging plate is placed across the alveolar cleft, even with adequate bone stock in the cleft, to stabilize the site and prevent uncoordinated movements of the maxillary segments.

Osteotomies

- Marking the medial canthal periosteal insertions with gentian violet or methylene blue prevents overdissection of soft tissues at the nasofrontal bridge and midline structures that can result in difficult-to-correct deformities.
- Mobilization of the Le Fort II transport segment, irrespective of osteotomy pattern chosen, should proceed via a two-operator approach.
- Capture an adequate amount of the malar eminence with the lateral osteotomy to provide stability of the infraorbital component of the quadrangular Le Fort II segment and avoid unfavorable fractures through the antrum.
- One operator should perform controlled movements with Rowe disimpaction forceps, while gradual mobilization of the segment is

performed by the second surgeon to mitigate unfavorable fracture patterns.

Distractors for Le Fort II osteotomy

- The use of the skull model with Le Fort II osteotomies is imperative; an ill-placed osteotomy may compromise the placement of the internal maxillary distraction device.
- Outlining the location of the osteotomies and temporarily placing the internal devices on the skull model avoids an inadequate bone platform for the zygomatic footplate.
- Placement of internal maxillary devices following completion of the osteotomies and disimpaction of the central midface is facilitated by placing a landmark screw on both the zygomatic footplate and the inferior maxillary plate of the device at the initial fitting in situ and prior to completion of osteotomies.
- The screws are removed and returned to the original holes after removal of the device.
- These screws are maintained during the bone cuts and then removed and reinserted into the original screw hole after the device is replaced appropriately (see **TECH FIG 3C,D**).
- If internal distraction techniques are used, Bollard plates, C-plates, or TADs attached to class III intermaxillary elastics prevent rotation of the midface during transport.

POSTOPERATIVE CARE

- Airway ICU management
 - Patients are transferred from the OR to the ICU. Extubation is possible in most patients. Excessive bleeding, concerns about airway, or prolonged operative time may warrant continued intubation.
 - IV steroids are given postoperatively for 48 hours to mitigate peak soft tissue and airway edema.
 - Perioperative antibiotics are given to cover oral and sinus flora for 7 days postoperatively.
 - Head of bed is elevated to more than 30 degrees.
 - Pain and anxiolytic management should be employed via continuous drips or administered as needed, and tailored to the patient's convalescence.
 - In patients with significant syndromic midface dysmorphism, severe preoperative obstructive sleep apnea, or submental intubations, extubation in the OR with easy access to anesthesia staff and advanced airway adjuncts should be considered.

■ Distraction

- We recommend a latency period of 5 days.
- Distraction is instituted on the morning of POD 5 at 0.5 mm twice daily (1 mm/d).
- Family members are instructed on how to perform rotation of the activating arms.
- The active phase of distraction averages 10 to 20 days (10 to 20 mm).
- If preoperative asymmetries exist, differential advancements of the activating arms may be required to achieve optimal facial harmony.
- Regular follow-up with clear communication from family via pictures can guide the distraction interval.
- Unlike advancement, the goal of distraction is not ideal occlusion, but midface harmony in profile. Occlusion is formalized via either postoperative orthodontic treatment or formal orthognathic surgery.
- Following completion of distraction, the activating arms can generally be removed in clinic.
- We recommend a consolidation phase of 3 months prior to device removal.
- If an internal Le Fort I level device is utilized for the Le Fort II distraction, the device can be removed with a vestibular incision.
- If Bollard plates, C-plates, or TADs have been used, they are removed simultaneously.
- Lateral canthopexies or lid-tightening procedures can be employed at this stage to complete reconstruction.
- If vertical orbital dystopia has resulted from the advancement, bone grafting (eg, split calvarium) of the orbital floor can be performed to achieve symmetry.
- Patients with severe obstructive sleep apnea should have a postoperative sleep study to assess breathing improvement; continuous positive airway pressure, or supplemental oxygen may no longer be required.

OUTCOMES

- Midface distraction distances ranged from 8 to 21 mm.
- Skeletal relapse is a significant concern, but long-term data are scant. Swennen et al.¹⁴ reviewed 285 articles on DO between 1966 and 1999, which included mandibular, maxillary, midface, and craniofacial distraction.
- Of the 96 patients identified who underwent midface or cranial distraction, only 19 patients had data on relapse.

- Of these 19 patients, only 2 (10.5%) demonstrated mild relapse.
- Much of the historical data suggest that unacceptably high rates of relapse after midface advancement were secondary to:
 - Underappreciation of the contradictory force vectors of the midface soft tissue envelope
 - Formal advancements of more than 10 mm prior to the advent of DO
 - Underuse or nonutility of at least 8 weeks of postoperative intermaxillary fixation with occlusal splints
 - Poor cortical bony stock for plate fixation in certain osteotomy patterns
- Relapse rates have been mitigated due to adherence of several principles:
 - Current use of internal and external DO techniques that allow for interval histogenesis of the midface soft tissue envelope
 - Guidance of the midface transport segment via halo device, intraoral Bollard plates, C-plates, or TADs
 - Adherence to 8 or more weeks of IMF in cases of formal advancement

COMPLICATIONS

- Infection
- Bleeding
- Bony malunion
- Nonunion
- Premature consolidation
- Skeletal instability
- Relapse
- Device failure
- Development of velopharyngeal incompetence
- Injury to the infraorbital nerve
- Partial or complete avulsion of the medial canthal tendon
- Injury to the nasolacrimal system

CHAPTER Le Fort III Advancement

Ghassan S. Abu-Sittah and Rawad S. Chalhoub

DEFINITION

- Le Fort III, first described by Rene Le Fort in 1901, is a pattern of craniofacial fractures that involves the nasofrontal suture, traverses the orbital floor, and crosses the zygomaticofrontal suture and zygomatic arch (**FIG 1**).¹
- In the 1960s and 1970s, Gillies and Tessier applied Le Fort's classification to facial osteotomies for the treatment of patients with midface hypoplasia.
- Le Fort III osteotomy with advancement, also known as craniofacial disjunction, is currently used for the correction of functional and aesthetic problems in patients with craniofacial dysostosis syndromes such as Crouzon, Apert, or Pfeiffer syndromes.
 - These conditions usually present with midfacial retrusion, shallow orbits, exorbitism, malocclusion, obstructive sleep apnea, and facial imbalance (**FIG 2**).
- Le Fort III advancement restores normal midface projection, re-establishes normal dental occlusion, increases the vertical dimensions of the face, and corrects exorbitism.

ANATOMY

- Normal facial growth depends on the coordinated expansion of the brain and overlying skeletal elements.
- The skull is relatively well developed at birth to protect the brain, whereas the facial skeleton continues to grow during childhood to accommodate dental development, orbital modeling, and airway formation.

FIG 1 • Pattern of Le Fort III fracture pattern.

- Cranial dysostosis describes syndromic craniosynostoses in which suture involvement includes the cranial vault, cranial base, and midface skeletal structures.
- Midface skeletal hypoplasia leads to both functional and cosmetic problems.
- Le Fort III advancement is generally required in these patients.

PATHOGENESIS

- Mutations of FGFR genes 1 to 3 lead to syndromic craniosynostoses, including Apert, Pfeiffer, Crouzon, Beare-Stevenson, Jackson-Weiss, Crouzon with acanthosis nigricans, and Muenke syndromes.²
- Environmental causes include paternal occupation, maternal age, exposure to tobacco smoke, and medications during pregnancy, including nitrofurantoin and warfarin.³

NATURAL HISTORY

- Craniosynostosis occurs in an estimated 1 out of every 2000 live births; it can occur as an isolated condition or part of a syndrome.
- Syndromic craniosynostosis affects 1:30 000 to 1:100 000 live births.⁴
- The midface hypoplasia in these conditions is progressive, becoming more

noticeable as the patient grows.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Craniofacial dysostosis patients suffer from a series of sequelae from growth abnormalities.
- Increased intracranial pressure (ICP) can occur as a result of the rapidly growing brain during infancy with limited space for expansion.
- Untreated ICP can cause papilledema and optic nerve atrophy, which can eventually lead to blindness.
- Vision problems may also occur secondary to exorbitism (exophthalmos) leading to corneal exposure with ulceration.³
- Dental, occlusal, and hearing deficits are higher in patients with craniofacial dysostosis than in the general population.²
- The most severe consequence of midface deficiency is obstruction of the developing airway, with narrowing of nasal and nasopharyngeal spaces, leading to increased airway resistance.⁵
- Newborns are obligate nasal breathers; airway obstruction forces them to breathe through the mouth, resulting in an inability to feed and breathe simultaneously. These newborns are at high risk for malnutrition and failure to thrive.

FIG 2 • A. Exorbitism secondary to shallow orbits. **B,C.** Lateral views of a patient with Apert syndrome. Midfacial retrusion and shallow posterior fossa are evident.

- Patients with severe symptoms, generally obstructive sleep apnea or exorbitism, may require a combination Le Fort III advancement with cranial advancement. Monobloc advancement is preferentially performed as a distraction procedure.⁶
- Patients who are mildly affected undergo Le Fort III advancement at skeletal maturity.

IMAGING

- Preoperative imaging required for patients undergoing Le Fort III advancement includes
 - Anteroposterior and lateral x-rays
 - Panoramic x-rays
 - Two-dimensional (2D) and three-dimensional (3D) CT scans (**FIG 3**)
- These images will demonstrate midface hypoplasia, as well as the various anomalies associated with the cranial sutures.
- CT scans are the preferred imaging modality and can be used with computer-aided design and modeling for preoperative planning to optimized the surgical approach.⁷

SURGICAL MANAGEMENT

- In planning and timing of the Le Fort III advancement in patients with craniofacial dysostosis, the experienced surgeon should take several factors into account.

FIG 3 • 3D CT reconstruction of a patient with midfacial hypoplasia and malocclusion.

- Age at presentation, the presence of functional problems such as upper airway obstruction, the presence of elevated ICP, and the tendency of growth restriction in facial bones undergoing surgical manipulation
- The main steps of the Le Fort III procedure include
 - Osteotomies using a Le Fort III design through the frontozygomatic suture, floor of the orbit, and the nasion
 - Mobilizing the Le Fort III segment
 - Internal fixation to zygomatic arch
- The objective of the procedure is to address functional problems (breathing, feeding, ocular), advance and normalize the occlusion, and improve facial aesthetics.⁵

Preoperative Planning

- Preoperative imaging helps planning for the surgery, such as using CT scans with computer-aided design and modeling to create stereolithographic models for optimization of osteotomies and designing patient-specific implants for perfect bony match.
- Communicate openly and effectively with parents regarding expectations before, during, and after the surgery.

- A multidisciplinary team approach, with pediatric intensivists, pediatric anesthesia, and orthodontics should be assembled to perform the surgery.
- Cross-matched blood should be available in the operating room.
- Appropriate plating systems must be available.
- Appropriate surgical instruments must be available.

Positioning

- Patients are positioned supine with hands by their sides.
- A single IV is started.
- Orotracheal intubation is utilized, but nasal intubation may be necessary in certain conditions.
- A Foley catheter is placed to assess fluid status.
- A warming blanket is used for temperature regulation.
- Eyes are protected with moisturizing ointment and sterile plastic adhesives placed over the cornea after the skin has been prepped.³
- Preoperative antibiotics and steroids are administered.
- Tranexamic acid should be administered, because of evidence that it effectively reduces perioperative blood loss.⁸

Approach

- Approach is through a coronal incision.

TECHNIQUES

■ Exposure

- A coronal incision is marked on the scalp behind the hairline and injected with 0.5% lidocaine with epinephrine 1:200 000 based on pediatric weight guidelines (**TECH FIG 1A**).
- Exposure is obtained of the frontotemporal skull, lateral and medial orbits, nasion, zygomatic arch, and zygomatic body (**TECH FIG 1B**).⁵
- Dissection in the subgaleal plane is deepened subperiosteally about 1 cm above the orbits to preserve the supraorbital and supratrochlear nerves.
- To provide adequate visualization of the inferior orbital margin along with the lateral orbital wall and orbital floor, a subciliary incision is preferred.

Special care should be taken to protect the cornea from abrasions.

- An upper buccal sulcus incision provides access to the infraorbital region, maxilla, malar body, and anterior aspect of the malar arch. It is important to leave a cuff of mucosa on the alveolar aspect for easy closure of the incision.

Osteotomies and Advancement

- Osteotomies are performed using the reciprocating saw through the zygomatic arch, followed by the lateral, inferior, and medial orbital walls.
- These cuts are then extended to the anterior region of the inferior orbital fissure and across the orbital floor.
- We complete the osteotomy by separating the medial orbital wall posterior to the nasolacrimal duct. The medial canthal tendon is left intact during this maneuver.
- Pterygomaxillary disjunction via sectioning the maxillary tuberosity from the pterygoid plates from above. Special care should be taken because in several craniosynostotic syndromes a dense bony block exists (**TECH FIG 2A**).
- A broad osteotome is used to cut the nasal septum.
- After performing the osteotomies, the facial skeleton is freely mobile and can be placed to its desired position using the Rowe forceps (**TECH FIG 2B**).
- The surgeon must be cautious during the mobilization of the Le Fort III as this step carries high morbidity in blood loss.

Fixation and Completion

- Intermaxillary fixation is applied with an acrylic wafer to hold this segment in place until bone grafts are set in place.
- Bone grafts are harvested from either the calvarium or the ileum and designed to fit in the space created by the advancement at the zygomatic arches, lateral orbital wall, orbital floor, and nose.
- Bone grafts are secured in the desired position with titanium plates and screws.
- IMF is released and the soft tissue is released and resuspended with lateral canthopexies (**TECH FIG 3A**).
- A Jackson-Pratt drain is placed.

TECH FIG 1 • A. Coronal incision marked on the scalp. **B.** Exposure of the calvarium and facial skeleton.

TECH FIG 2 • A. Pterygomaxillary disjunction. **B.** Mobilization of the midfacial skeleton using the Rowe forceps.

TECH FIG 3 • A. Lateral canthopexy. The subciliary **(B)** and superior buccal sulcus **(C)** incisions. **D.** Frost suture.

- The coronal flap is closed in layers.
- Buccal sulcus and subciliary incisions are closed in layers, with meticulous care in closing the periosteum when using the subciliary incision (**TECH FIG 3B,C**).
- A nasopharyngeal airway is placed as well as a nasogastric tube for postoperative feeding.
- With the expected periorbital edema following such a procedure, Frost sutures are placed to prevent ectropion and corneal damage that would result from the edema (**TECH FIG 3D**).

PEARLS AND PITFALLS

Physical findings

- Midfacial hypoplasia can be accompanied by severe symptoms such as obstructive sleep apnea, increased ICP, and exorbitism.

Technique

- The craniofacial surgeon makes use of the naturally occurring weaknesses along suture lines to separate the facial bones into subunits.
- Infiltrating the facial soft tissues with a tumescent solution containing Harmtan, Xylocaine, Hyalase, adrenaline, triamcinolone, and Marcaine can significantly reduce postoperative swelling.
- A posterior flap may also be raised when additional exposure of the calvarium is needed.
- Protection of the brain, meninges, and venous sinuses is crucial in all craniofacial operations. Dural lacerations should be meticulously repaired in order to prevent postoperative CSF leaks.
- To prevent migration of the plates and screws as a result of bone growth, dissolving plates and screws made of polylactic acid polymers should be used.

Postoperative

- Hypovolemia is the most common problem after Le Fort III advancement. Signs include tachycardia, delayed capillary refill (less than 2 s), cool peripheries, and hypotension. Treat hypovolemia by giving an immediate fluid bolus of 10 mL/kg.
- Patients with a history of feeding difficulties and borderline swallowing status presurgery must be closely monitored postsurgery for potential feeding difficulties.
- All contact sports should be avoided for at least 3 months.

FIG 4 • Before (**A**) and after (**B**) photos of a patient with midfacial hypoplasia who underwent a Le Fort III advancement.

POSTOPERATIVE CARE

- Postoperative oral feeding is limited to water for the first week with liquid feeding via the nasogastric tube until the nasopharyngeal airway is removed.
- A soft diet is introduced and continued for the next 3 months while consolidation of the osteotomies is taking place. Follow-up CT scans are done 12 to 18 months postoperatively unless the patient has neurologic deterioration. For postoperative hematomas or hydrocephalus, an MRI is preferred over the risks of the ionizing radiation from CT scans.

OUTCOMES

- Le Fort III advancement achieves midface advancement anywhere between 8 and 12 mm⁹ (**FIG 4**).
- Adequate fixation of the osteotomies decreases the relapse rates of the advancement.^{9,10}
- Pseudorelapse is observed when the rate of mandibular growth is greater than that of the maxilla. This can be managed with a subsequent Le Fort I after skeletal maturity.¹⁰

COMPLICATIONS

- Nerve injuries, including transection of the infraorbital nerve
- Ptosis secondary to facial nerve injury
- Partial anosmia
- Strabismus⁵
- Respiratory distress necessitating tracheostomy
- Infection of hardware
- Cerebrospinal fluid leakage with fistula formation
- Visual loss due to nerve compression from a retro-orbital hematoma

27 Le Fort III Osteotomy With External Distraction

CHAPTER

Gökhan Tunçbilek

DEFINITION

- The Le Fort III osteotomy corrects midface retrusion for patients with syndromic craniosynostosis and after the sequelae of Le Fort III fractures.
- Gillies performed the first Le Fort III advancement in a patient with Crouzon syndrome.¹
 - Tessier refined the technique using Le Fort III fracture lines as a guide for osteotomies (**FIG 1A–E**).²
- The first attempts of combining the Le Fort III procedure with distraction osteogenesis were in the mid-1990s and have become an effective, reliable technique for managing patients with midface hypoplasia.^{3,4}
- Midface retrusion may cause significant functional, morphological, and psychological impairment in patients with syndromic craniosynostosis.
 - All the parts of the face and forehead are affected, leading to breathing difficulties and ocular and occlusal problems, all of which impair the life of the patient.
 - Anterior movement of the facial skeleton addresses all of these problems.
- Combining Le Fort III osteotomies with gradual distraction overcomes soft tissue resistance and produces skeletal corrections greater than 10 mm, which is the upper limit for conventional osteotomies with rigid fixation alone.⁵

ANATOMY

- The midface consists of a maxilla-ethmoidonasal complex located between the two zygomas. This complex is suspended from the middle portion of the frontal bone anteriorly and the anterior cranial fossa posteriorly. The midface region is bounded above by a transverse line connecting the zygomaticofrontal sutures,

passes through the frontomaxillary and frontonasal sutures, and is defined inferiorly by the occlusal plane of the maxillary teeth. Posteriorly the region is limited by the sphenoethmoidal junction and includes the free margins of the pterygoid plates inferiorly.

- The skull and the facial skeleton have a fixed relationship. The facial skeleton is connected to the pterygoid process through the intermediate palatine bones and to the body of the sphenoid through the septonasal strut.
- It is fixed laterally by the zygomatic arch and suspended from the frontal bone by the processes of the zygomatic bones and of the maxilla (**FIG 2**).
- The facial region is subject to the vertical strains of mastication and therefore arranges its osseous trabeculae vertically and horizontally in areas of strength (*pillars*), which are separated by zones of weakness.
- The facial complex is weakened by the presence of two kinds of cavities—air cavities (sinuses) and receptor cavities (orbits)—and sutures.
- The sinuses are accessories to the nasal fossa, whose extent determines the degree of facial skeletal pneumatization; the receptor *orbits* house the peripheral receptors of vision.

PATHOGENESIS

- Midface retrusion is a major finding of syndromic craniosynostosis, caused primarily by autosomal-dominant FGFR mutations and MSX2 and TWIST 1 mutations.
- Most infants born with syndromic craniosynostosis present with bilateral coronal suture synostosis and a variable degree of midface retrusion.

FIG 1 • A–E. Osteotomy lines of traditional Le Fort III

osteotomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A family history or a resemblance of the child to a relative suggests an inherited trait.
- Pregnancy and birth histories are helpful with patient management.
- Lethargy, vomiting, and difficulty seeing or following objects may be clues to underlying neurological disorders.
- Seizure activity and developmental delays indicate abnormal brain function.
- Malar flatness and midface retrusion is a common constituent of syndromic craniosynostosis and secondary to growth restriction of the cranial base.
- Midface recession and concave profile can be severe, resulting in obstruction of nasopharyngeal airflow and respiratory distress (**FIG 3**).

- An evaluation of the extremities is essential in patients with syndromic craniosynostosis. Syndactyly is a major component of Apert syndrome. Abnormalities of the thumbs and toes are elements of Pfeiffer and Carpenter syndromes.

IMAGING

- Computed tomography (CT) is useful to determine evidence of sutural fusion, signs of increased intracranial pressure, and indications of pathologic neuroanatomy.
- Three-dimensional (3D) CT scan provides a clear image of the bony anatomy and deformities of the craniofacial skeleton (**FIG 4A**) and can be combined with plain films for surgical planning (**FIG 4B**).
- MRI is necessary only if further detail of the brain is required or if a Chiari malformation exists.
- Structural anomalies of the central nervous system should be evaluated by a pediatric neurosurgeon.

FIG 2 • Separation of the facial skeleton from the skull and skull base at the Le Fort III level.

FIG 3 • A,B. Malar flatness and exophthalmos in a patient with Pfeiffer syndrome. **C.** The cranium has a trigonocephalic shape, and thumb printing can be seen on the lateral x-ray. The close positioning of the posterior pharyngeal wall to soft palate can lead to

airway compromise.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients undergoing Le Fort III distraction require a multidisciplinary team, including a plastic and craniofacial surgeon, ophthalmologist, otolaryngologist, and orthodontist.
- The craniofacial surgeon and the orthodontist play important roles in the surgical planning and in managing the pre- and postintervention occlusion and appearance.⁶
- The treatment strategy of a child with syndromic craniosynostosis includes a series of operations separated over time responding to the growth and development of the craniofacial skeleton.
- This phased treatment plan is based on the differential growth patterns of the cranial vault, the midface, and the mandible. Institutional preferences and functional requirements may change the timing of these staged operations.
- Midface advancement using Le Fort III distraction is generally performed between 7 and 10 years of age.
- The degree of airway obstruction and exposure of the globes may accelerate timing of surgery to the midface.

Approach

- Advancement of the midface can be performed with a conventional Le Fort III osteotomy and rigid fixation or by using Le Fort III osteotomy with distraction.
- Le Fort III distraction has several advantages over the traditional technique.
 - The soft tissue envelope limits mechanical advancement of the midface with the traditional procedure.
 - Resistance of soft tissue is generally manageable for advancements of less than 10 mm.⁵
 - Elimination of soft tissue resistance using distraction leads to lower relapse rates than conventional midface advancement techniques.⁷
 - Conventional Le Fort III osteotomy often requires repeat surgery at completion of facial skeletal growth. Le Fort III overdistractor can compensate for future growth, avoiding the need for repeat surgery.⁸
 - Le Fort III distraction eliminates the need for bone graft, thereby decreasing

length of the procedure and eliminates donor-site morbidity. There is also significant decrease in blood loss and postoperative pain after the operation and hospital stay is shorter.⁷

- Le Fort III distraction can be performed with either internal or external devices.
- Internal systems are semiburied, laterally placed devices, and may be tolerated better than external devices.
- Internal systems limit control over the midfacial skeletal segments, especially in vertical and transverse vectors. Lack of control over the central midfacial structures tends to push the zygomas forward and create midline collapse and increased facial concavity.⁹
- The author's preferred technique is external distraction.
- Skull-anchored external halo distractors allow multidirectional, unlimited distraction, and multiplanar adjustability of distraction forces at any time during the distraction procedure.
- The surgeon has the ability to focus treatment on only the affected skeletal region, and there is no bone grafting or internal fixation device required.

FIG 4 • A. 3D CT view of a patient with Apert syndrome. Bilateral coronal suture synostosis (note the ridging of the coronal sutures) and a large anterior fontanelle are

common. **B.** Severe midface retrusion and class III malocclusion of a patient with Crouzon syndrome.

TECHNIQUES

■ Le Fort III Advancement With External Distraction

Exposure

■ Incisions

- The bitemporal (or bicoronal) zigzag incision provides exposure to the frontonasal junction, medial orbital wall, lateral orbital rim, and lateral orbital wall to the retromolar groove including the zygomatic arch (**TECH FIG 1A**).
- Infraorbital subciliary incisions provide exposure to the inferior orbital rim and the floor of the orbit (**TECH FIG 1B**).
- The superior vestibular sulcus incision provides exposure to the pterygomaxillary junction (**TECH FIG 1C**).
- After injecting local anesthetic with adrenaline at all sites, the bitemporal incision is performed first.
- Subperiosteal dissection is used and the coronal flap is turned down.

TECH FIG 1 • Combined incisions for the Le Fort III osteotomy include bicoronal **(A)**, subciliary **(B)**, and upper buccal sulcus **(C)**.

- The osteotomy sites are exposed with subperiosteal dissection around the superior half of the orbit from the nasofrontal suture to the zygomatic arch.
- The temporalis muscle is left in situ except in the areas posterior to the lateral orbital wall and the zygomatic arch.
- The subciliary and superior vestibular sulcus incisions are made in standard fashion.

Osteotomies and Mobilization

- Nasofrontal osteotomy is made with a reciprocating saw a few millimeters below the nasofrontal junction extending into the medial nasal wall, behind the posterior lacrimal crest (see **FIG 1A,B**).
 - The oblique section of the nasal septum is osteotomized with a curved osteotome.
- The lateral orbital wall osteotomy is made with a reciprocating saw, from the zygomaticofrontal suture to the lateral orbital wall toward the inferior orbital fissure.
 - A 4-mm osteotome is used for the orbital floor between 1 and 2 cm posterior to the orbital rim and behind the lacrimal crest.
- The same osteotome is used for the medial wall osteotomy behind the medial canthus to complete the osteotomy around the orbital contents.
 - The zygomatic arch is reached from the bitemporal incision superiorly a few centimeters below the lateral orbital rim and also sectioned with the reciprocating saw (see **FIG 1B**).
- A long, curved tip osteotome is used for pterygopalatine disjunction using the upper buccal sulcus incision (**TECH FIG 2A**).
- Once complete osteotomies are confirmed, the Rowe disimpaction forceps are used to complete the down-fracture (**TECH FIG 2B,C**).
 - Complete mobilization should be performed to stretch all soft tissues and separate remaining bony connections.

TECH FIG 2 • A. Pterygomaxillary disjunction is performed to complete anterior mobilization of the midface. Rowe disimpaction forceps are used to move the facial skeleton anteriorly **(B)** to complete the down-fracture of Le Fort III osteotomies **(C)**.

- Incomplete osteotomies may lead to unfavorable fractures and require higher forces for separation during the activation phase.

External Distraction Device Placement

- After adequate mobilization of the Le Fort III segment, for inferior anchorage, a custom-made rigid intraoral splint is attached to the maxillary teeth (**TECH FIG 3A**).

- For superior anchorage, special screw-plate devices may be an option (**TECH FIG 3B**).
- Alternately, the distractor system can be fixed directly to the infraorbital rims using a surgical wire (**TECH FIG 3C**).¹⁴
- In younger patients, disjunction of zygomaticomaxillary junction may occur when distraction is initiated.
 - To avoid this, the junction can be reinforced with a titanium plate, with the surgical wire placed around the plate.
- After placement of the traction wires, all incisions are closed in layers and drains are placed under the frontal flap.
- The halo of the rigid external device is assembled and adjusted for the width of the neurocranium. It is rigidly fixed around the head with three scalp screws on each side.
- Continuous traction force of 4 kg is sufficient to distract the midface after a complete Le Fort III osteotomy (**TECH FIG 3D,E**).¹⁰
- The halo is placed before extubation, but vertical rod and horizontal bars are placed on the 5th postoperative day before distraction is initiated. This maneuver allows the anesthesia team to extubate the patient safely (**TECH FIG 3F**).

A

B

C

TECH FIG 3 • **A.** A custom-made rigid intraoral splint is attached to the maxillary teeth for the inferior level of anchorage. **B.** Screw and plate combinations designed by the manufacturer are placed through the subciliary incisions. **C.** A surgical wire connected directly to the infraorbital rim, immediately lateral to the infraorbital nerve. **D,E.** Custom-made spring scales attached to the distraction units. A continuous tension force of 4 kg is found to be sufficient to generate an advancement of 1.5 mm to the Le Fort III segment. **F.** Lateral view of a patient with Crouzon syndrome. The external halo distractor is anchored to the skull, and distraction units are attached to the midface during the activation period.

■ Modification of Technique for the Lateral Orbital Wall

- Le Fort III osteotomy with distraction results in further anterior positioning of the Le Fort III segment.
 - Thus, a step may occur between the superior-most margin of the advancement segment and the upper part of the lateral orbital rim above the osteotomy line (**TECH FIG 4A**). This step can be felt easily with palpation and may influence the appearance of the patient negatively.
- To modify the described technique, another osteotomy line is added 1.5 cm inferior to the original lateral wall osteotomy,¹² creating a bone fragment at the lateral wall.
 - This segment acts like a bridge between the frontal bone and the Le Fort III segment.
- The bone fragment is loosely attached to the frontal bone superiorly and Le Fort III segment inferiorly with a 4-0 nonabsorbable suture (**TECH FIG 4B–D**).
 - This loose attachment allows anterior movement of the Le Fort III segment with the inferior pole of the bone fragment and avoids unexpected movement of the bone fragment into another location.

TECH FIG 4 • A. 3D CT of the potential step that may occur between the superior-most margin of the advancement segment and the upper part of the lateral orbital rim above the osteotomy line. This step can be felt easily with palpation and may influence patient appearance. **B,C.** The bone segment, created at the lateral wall, will act like a bridge between the frontal bone and Le Fort III segment. **D.** Postoperative 3D CT of the patient showing the smooth connection of the osteotomy segments.

PEARLS AND PITFALLS

Physical findings

- Perform an ophthalmologic examination for functional and visual status of the eyes preoperatively, and document findings.
- Obtain appropriate imaging.
- Discuss each patient preoperatively with anesthesia, ophthalmology, and neurosurgery colleagues.

Technique

- It may be difficult to decide whether to perform Le Fort III advancement with or without distraction. Even for advancement distances less than 10 mm, distraction osteogenesis has demonstrated improved results.
- Suture the endotracheal tube to the columella and place surgical gauze intraorally to secure the airway while performing osteotomies.
- Meticulous bony technique is mandatory to avoid damage to the orbital contents.
- It is necessary to have complete osteotomy lines and full mobilization of the Le Fort III segment at the end of the operation. Check the osteotomy lines twice, especially the posterolateral walls of the maxilla, pterygopalatine junction, and nasal septum.
- While positioning the halo of the external distractor, place the fixation screws carefully. It is easy to apply too much torque using a wrench; therefore, if possible, place the screws manually.
- If there is any doubt regarding intracranial pin migration (persistent nausea and vomiting during the early postoperative period) after radiologic examination, check pin depth and change the position of the pins and/or halo, as necessary.

Postoperative care

- The early postoperative period may be troublesome because of soft tissue edema.
- External halo distractors are reliable and robust devices; therefore, device failure is rare.
- Wires connecting the Le Fort III segment to distraction units may break during activation and should be repaired immediately.
- Although overall characteristics of patients with syndromic craniosynostosis are similar, long-term results after Le Fort III distraction of Crouzon patients are better than others (including patients with Apert and Pfeiffer syndrome).

Therapy

- Postoperative orthodontic therapy is needed to correct occlusal problems and for fine adjustments.

POSTOPERATIVE CARE

- Distraction protocol
 - A 5-day latency period is followed by an activation rate of 1 mm/d.
 - Activation is completed when the desired amount of transport has been achieved.
- Plain radiographs are performed preoperatively and weekly during the postoperative period to follow the status of the bony segments and the distraction process
- The consolidation period may vary among patients and can be up to 12 weeks.
- Midface advancement can be associated with considerable blood loss and may be further complicated by challenging airways.
 - Postoperative care of these patients requires comprehensive intensive care management.

OUTCOMES

- Distraction is a safe and effective way of reconstructing the craniofacial skeleton using inductive bone generation rather than traditional grafting and repair and can be viewed as an endogenous form of tissue engineering.⁷
- Le Fort III distraction effectively treats respiratory and ocular problems.
- Normalization of appearance is also a major goal of the procedure. Midface hypoplasia is successfully corrected.
 - Patients should have an Angle class I occlusion after distraction (**FIGS 5 and 6**).
- Postoperative relapse may occur in up to one-third of patients and generally develops within the first 6 months after distraction.¹¹

A

B

C

D

FIG 5 • Preoperative (**A,B**) and postoperative (**C,D**) views of a patient with Crouzon syndrome after Le Fort III osteotomy with external distraction. The advancement was less than 10 mm, and the results are stable after 2 years. Preoperative (**E**) and postoperative (**F**) intraoral photos.

FIG 6 • Preoperative (**A,B**) and postoperative (**C,D**) views of a patient with Crouzon syndrome. The patient underwent rhinoplasty several years after the Le Fort III osteotomy with external distraction. Lateral cephalograms taken preoperatively (**E**), during

activation (**F**), and postoperatively (**G**) show that upward rotation of the maxilla created an open-bite deformity, which may be seen frequently, when the inferior anchorage is through the rigid intraoral splint. Postoperative orthodontic therapy resulted in angle class I occlusion.

- Long-term stability may be affected by the phenomenon known as pseudorelapse, which is defined as ongoing normal growth of the mandible combined with diminished growth of the maxilla, giving the perception of maxillary relapse.¹²
- Such relapse is typically seen in patients undergoing Le Fort III distraction during childhood and is managed at skeletal maturity with Le Fort I orthognathic surgery.
- Although major improvements can be achieved with Le Fort III distraction in patients with syndromic craniosynostosis, normalization of facial aesthetics may be difficult to obtain in patients with severe bony and soft tissue deformities (**FIG 7**).

COMPLICATIONS

- Superficial infections, mostly around the pin sites at the cranium
- External halo complications, including mechanical failure, pin loosening, frame migration, and intracranial migration of the fixation pins with dural violation (**FIG 8A,B**)
 - This last complication can be avoided by placing temporary titanium mesh or resorbable plates in the temporal areas at the sites of pin fixation (**FIG 8C–E**).¹³
- Ectropion after subciliary incision
- Excessive bleeding requiring transfusion
- Maxillozygomatic disjunction may occur in young patients and can be avoided by strengthening the suture with microplates and screws.
- Globe injury
- Infraorbital nerve injury
- Dural injury with subsequent cerebrospinal fluid leak
- Incomplete or atypical fractures

FIG 7 • Preoperative (A,B) and postoperative (C,D) views of a patient with Pfeiffer syndrome. Preoperative (E) photo. Angle class I occlusion is obtained after surgical and orthodontic therapy.

FIG 8 • Photograph (A) and plain x-ray (B) of a patient with intracranial migration of fixation pins after trauma. The distraction and recovery periods were completed without complication. C–E. Resorbable plates were placed in both temporal areas for pin fixation.

Minimal Access Le Fort III Osteotomy for Midface Hypoplasia

28

CHAPTER

Scott J. Rapp and Christopher B. Gordon

DEFINITION

- Midface hypoplasia can lead to significant aesthetic and functional airway compromise.
- Le Fort III distraction osteogenesis is a useful surgical approach to address hypoplasia and facial dysmorphism at skeletal maturity or when severity of symptoms warrants earlier intervention.
- A Le Fort III approach involves osteotomies to the floor/lateral/medial wall of orbit, nasal bones, zygomaticofrontal suture, pterygoid plates of sphenoid, ethmoid, zygomatic arch, and posterior wall of maxillary sinus.

ANATOMY

- Midface hypoplasia (**FIG 1**) is characterized by:
 - Facial disharmony
 - Malar deficiency and concavity to profile
 - Exorbitism, lack of globe protection
 - Class III occlusion
 - Posterior airway space (PAS) narrowing
 - Dental crowding

PATHOGENESIS

- Events leading to severe craniofacial skeletal dysplasia are likely multifactorial but are believed to be associated with abnormalities in neural crest cell development and migration.¹
- Most are associated with genetic syndromes, but occasionally they may be

sporadic.²

- Midface sutures such as the speno-occipital suture may prematurely fuse leading to growth disturbances.³
- Genes associated with midface hypoplasia are the fibroblast growth factor receptor genes (*FGFR2*, *FGFR3*), twist-related protein gene (*TWIST*), and treacle ribosome biogenesis factor 1 gene (*TCOF1*).¹
- Midface hypoplasia is often observed with concomitant craniosynostosis, most often with bicoronal synostosis seen in syndromic patients:
 - Apert (*FGFR2*)
 - Crouzon (*FGFR2*)
 - Saethre-Chotzen (*TWIST*)
 - Meunke (*FGFR3*)
- Other syndromes leading to maxillary hypoplasia include Treacher Collins syndrome and craniofacial microsomia (hemifacial microsomia, Goldenhar syndrome).
- Neurologic dysfunction may be present including:
 - Hydrocephalus/ventriculomegaly
 - Gyral abnormalities
 - Hypoplastic/heterotopic white and gray matter
 - Corpus callosal agenesis
 - Kleeblattschadel/megalocephaly

NATURAL HISTORY

- Surgical approaches to the midface in syndromic patients were first reported by Gilles in the 1950s and then advanced through Paul Tessier's work in the 1960s.⁴
- Midface osteotomies have been historically performed at skeletal maturity to prevent undergrowth or reduce relapse rates.
- However, distraction techniques provide greater bony movements and more structural stability at an earlier age to address life-threatening airway compromise and ocular exposure.

FIG 1 • Midface hypoplasia can have profound effects on projection **(A)**, occlusion and airway **(B)**, and eye protection **(C)**.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Clinical exam findings may include
 - Midface retrusion
 - Craniosynostosis
 - Exorbitism/shallow orbit
 - Keratitis/corneal ulcers
 - Lagophthalmos/scleral show
 - Orbital hypertelorism
 - Class III occlusion
 - Anterior open bite
 - Narrow arch/dental crowding

IMAGING

- Cephalometric consideration for PAS (**FIG 2A**)
- Nasopharynx
- Pterygomaxillare (pm) to posterior pharyngeal wall (upaw)
- Oropharynx
- Tip of uvula (U) to posterior pharyngeal wall (mpaw)
- Hypopharynx
- Tongue base (V) to posterior pharyngeal wall (lpaw)
- Plain film/CT exam findings (**FIG 2B**)
- Shallow orbits

- Hypertelorism
- Exotropia
- Bicoronal synostosis—brachycephaly
- Choanal stenosis/atresia

DIFFERENTIAL DIAGNOSIS

- Syndromes that may require Le Fort III advancement
- Crouzon
- Apert
- Pfeiffer
- Treacher Collins
- Nager

FIG 2 • Imaging **(A)** demonstrates posterior airway space narrowing that can be measured through cephalometrics **(B)** to determine distance required during distraction.

- Meunke
- Saethre-Chotzen
- Carpenter

NONOPERATIVE MANAGEMENT

- Severe midface hypoplasia observed in syndromic newborn may require early nonsurgical management.
- Airway compromise may be managed with:
 - Prone positioning
 - Positive pressure ventilation or assistance
 - Mandibular distraction for concomitant tongue-based obstruction
 - Globe protection
 - Taping
 - Eye lubrication

SURGICAL MANAGEMENT

- A multidisciplinary team is required for optimal surgical intervention, including:
 - Plastic surgery/oral surgery
 - Orthodontics
 - Genetics
 - Dentistry
 - Ophthalmology
 - Speech pathology
 - Otolaryngology and audiology
 - Social work and psychology

Preoperative Planning

- Planning between surgeon and orthodontist is critical to optimize the desired end point of centric occlusion.
- Virtual surgical planning (VSP) or model surgery assists in anticipated distance and vectors for distraction.
- Stereolithic models can assist with identification of permanent teeth and root location.

FIG 3 • Supine positioning with a shoulder roll and horseshoe headrest provides adequate access. Securing the endotracheal tube with circumdental, circum-mandibular, or transalveolar suturing/wiring to reduce intraoperative malposition of the endotracheal tube is recommended.

- Patient may require palatal expansion prior to Le Fort III osteotomy.
- Maxillary third molars may be removed prior to intervention; secondary Le Fort I osteotomy is anticipated to obtain class I occlusion.

- An ophthalmologic evaluation is required to assess for corneal ulceration and abrasion and to identify preoperative visual dysfunction (ie, strabismus, exotropia, V-pattern esotropia/exotropia).

FIG 4 • Access for Le Fort III osteotomies can be exposed through a traditional bicoronal incision **(A)** or transconjunctival incision with extended lateral canthotomies **(B)**.

- Identify symptoms of sleep apnea including frequent snoring, apneic episodes during sleep, daytime somnolence, or growth abnormalities.
- Perform a sleep study to determine preoperative apnea-hypopnea index (AHI) or respiratory distress index (RDI).
- Perform tracheostomy if central sleep apnea is observed.
- Imaging should include CT exam with 3D reconstruction for bone/soft tissue evaluation and MRI for intracranial evaluation.
- Anesthesia consultation is important to assess perioperative airway risk.
- Ear, nose, and throat (ENT) consultation for airway assessment.

Positioning

- Access to the midface can be accomplished with supine positioning and the use of a horseshoe headrest **(FIG 3)**.
- Rigid cranial fixation is not required.
- A shoulder roll assists in creating a level facial plane.
- Secure the airway with either circumdental, circummandibular, or

transalveolar suturing/wiring to reduce intraoperative malposition of the endotracheal tube.

- In mixed dentition, avoid placing suture or wire through the alveolus, which would result in tooth bud injury.
- Oral RAE endotracheal tube
- Turn the table 90 degrees to allow access to both sides of the patient.
- Proper pressure relief is necessary due to length of case. Use foam or gel under the occiput, elbows, hips, knees, and heels.
- Serial compression devices are used in older patients.

Approach

- Access to the midface is accomplished through a traditional coronal incision (**FIG 4A**) or extended transconjunctival incision (**FIG 4B**).
- The extended transconjunctival incisions may avoid intraoral incisions.

TECHNIQUES

■ Incision and Access to the Orbital Rim and Floor

- Clear corneal eye protectors are placed.
- The conjunctiva is infiltrated with 0.5% lidocaine with epinephrine 1:200 000 and 10 minutes are allowed to elapse.
- Medial and lateral traction stitches in the gray line of the lower lid help with identification of the lower lid tarsal border through retraction (**TECH FIG 1A**).
- An inferior lateral canthotomy is created sharply, extending 5 mm beyond the lateral canthus (**TECH FIG 1B**).
- Needle tip cautery with blend-cutting mode is used to divide the conjunctiva immediately inferior to tarsus.
- Bipolar cautery is used to coagulate prominent vessels in the dissection plane for controlled hemostasis.
- Cotton-tip applicators are used bluntly and atraumatically to develop a preseptal plane to the orbital rim (**TECH FIG 1C**).
- The periosteum at the orbital rim is divided with electrocautery with minimal anterior stripping of the maxillary periosteum.

- The orbital floor periosteum is elevated medially up to the nasolacrimal duct insertion, which is carefully identified and preserved. Dissection continues beyond the duct to the nasal and ethmoid bones.
- Laterally, subperiosteal dissection is extended up to the zygomaticofrontal suture.

TECH FIG 1 • **A.** With extended transconjunctival incisions, medial and lateral tarsal retraction stitches assist in developing the appropriate preseptal plane to the orbital rim. **B.** Inferior lateral canthotomy. **C.** Orbital osteotomies are created under direct visualization. A larger lateral window is created so that

the Sonopet can reach the pterygoids from the orbit.

■ Osteotomies, Pterygomaxillary Disjunction, and Midface Mobilization

- A Sonopet Ultrasonic Osteotome (Stryker, Kalamazoo, MI) allows for minimal soft tissue disruption and carefully controlled osteotomies.
- Selected tips are the Nakagawa knife, micro claw, or aggressive serrated tip; the protective sheath is removed to reduce the diameter of the orbital floor osteotomy required.
- With the lid retracted and all soft tissue protected from the exposed Sonopet shaft, the osteotomies are made medially from the most anteromedial aspect of the inferior orbital fissure to the lacrimal fossa. The osteotomy extends posterior to the insertion of the nasolacrimal duct (**TECH FIG 2A**).
- A transcutaneous incision is made over the nasofrontal junction to expose the position where the orbital floor osteotomy meets the nasal bone.
- The nasal bones and underlying perpendicular plate of ethmoid bone are cut with the Sonopet. This leads to minimal disruption to nasal mucosa.
- Alternatively, an osteotome can be used to make these cuts (**TECH FIG 2B**).
- The orbital floor osteotomy is then extended laterally and cranially to the level of the zygomaticofrontal suture.

TECH FIG 2 • A. The lateral orbitotomy is extended through the zygomaticofrontal junction. **B.** The nasofrontal osteotomy is accessed through a small stab incision. The osteotomy can be started with the Sonopet and checked for completion with an osteotome. **C.** The pterygomaxillary osteotomy is reached from the lateral orbital floor window. **D.** Correct placement and angle is confirmed by digitally palpating the tip of the Sonopet. **E.** To ensure adequate pterygomaxillary dysjunction, perform gentle passes to remove small portions of bone.

- Within the orbit, the lateral floor osteotomy is widened to facilitate pass of the Sonopet through the antrum to approach the pterygomaxillary junction (**TECH FIG 2C**).
 - The Sonopet is then obliquely angled from within the antrum of the maxilla to divide the posterolateral maxilla at the junction with the pterygoids (**TECH FIG 2E**).
 - The zygomatic arches are accessed from the lateral orbitotomy.
 - Alternatively, the arch can be cut transmucosally with an osteotome; however, this is not recommended due to oral contamination.
 - A 3-mm osteotome is used to ensure that all cuts are complete.
 - Down-fracture is possible by digital manipulation alone if osteotomies are performed correctly.
-

■ Rigid External Device Placement

- A rigid external device (RED) is placed in the horizontal plane as just above the superior helix of the ear.
- The screws are advanced by hand and turning stopped when “finger tight.”
- Two maxillary titanium L-plates are positioned over the zygomaticomaxillary buttress with the arms bent, curving around the soft tissue, and fixated to the RED by 24-gauge dental wire (**TECH FIG 3A**).
- Locking screws are used to fixate the plate transmucosally avoiding disruption of tooth roots (**TECH FIG 3B**).
- Orbital plates may be positioned along the inferior orbital rim to more evenly distribute the forces of distraction.

TECH FIG 3 • **A.** Titanium plates are placed transmucosally with locking screws (*arrow*). They are bent to prevent ulceration to the upper lip when distracting. **B.** Use of a rigid external device allows for multiple vector movements and extended distraction distance.

■ Distraction Protocol

- Distraction is started on postoperative day 1.
- Movement is 0.5 mm twice daily for 1 mm/day.
- Weekly lateral cephalograms performed at 72" follows progress of distraction.
- The consolidation period is 5 days before the RED, plates, and screws are removed.

PEARLS AND PITFALLS

Bony

■ Osteotomy plane

regenerate	■ Avoid intranasal or intraoral mucosal disruption to minimize bacterial contamination of the bone callus during distraction. ■ The Sonopet causes thermal injury to bone if stationary and is capable of burning through soft tissue, vessels, and nerves.
Technique	■ Incomplete osteotomy ■ The midface should be freely mobile using digital pressure alone. ■ Confirm all osteotomies with a 3-mm osteotome. ■ Tooth root disruption ■ Utilize screw lengths of 6 mm or less and refer to medical model for aberrant tooth locations.
Distraction protocol	■ It is the senior author's preference to forego a latency phase. ■ Movement can be up to 2 mm/d. ■ Confirm bony consolidation with CT.
RED on infant	■ Thin calvarial bone ■ Overtightening of screws may lead to inner calvarial table penetration. ■ Risks can include dural disruption, cerebrospinal fluid (CSF) leaks, or brain injury. ■ Mesh underlay can add thickness to areas of thin bone to prevent overpenetration.

POSTOPERATIVE CARE

- The patient should remain intubated and admitted to the ICU following surgery.
- Extubation may be performed with ENT/anesthesia at bedside once airway swelling has subsided or demonstration that PAS is improved in cases of severe sleep apnea.
- A nasogastric feeding tube may be used in severe cases but is often unnecessary for oral intake.
- Distraction can be continued as an outpatient, and consolidation can be confirmed with CT imaging.
- Weekly lateral cephalograms can be used to determine end point of distraction, with slight overcorrection by a few millimeters.
- The RED device and oral plates can be removed as an outpatient procedure following cessation of distraction.

OUTCOMES

- Average maxillary advancements of 16 mm have been reported (6–31 mm).^{5,6}

■ **FIG 5** demonstrates expected nasopharyngeal airway improvement.

FIG 5 • 3D reconstructions of the upper airway following distraction show improved volume and space.

- Soft tissue changes can drastically improve midface projection, occlusion, and globe protection (**FIG 6**).
- There is evidence that a reduction in the respiratory disturbance index or apnea/hypopnea index can be achieved in over 50% of patients^{6,7} (**FIG 7**).
- RED devices are tolerated well with proper education and counseling.

COMPLICATIONS

- Incomplete osteotomy
- Premature consolidation
- Zygomatic fracture during distraction
- Permanent tooth damage
- Excessive pressure on globe during pterygomaxillary osteotomy
- Nonunion following advancement
- Relapse of advanced bony segment
- Malocclusion
- Fracture propagation
- Blindness

FIG 6 • Soft tissue aesthetics are greatly enhanced with

successful Le Fort III distraction. **(A)** demonstrates pre-operative midface hypoplasia; **(B)** demonstrates improved facial form.

FIG 7 • Symptoms of obstructive sleep apnea can be mitigated or entirely corrected within posterior nasopharyngeal space after Le Fort III distraction.

Secondary Alveolar Bone Grafting of the Cleft Alveolar Defect in Cleft Palate

CHAPTER

Richard E. Kirschner, Michelle A. Scott, and Matthew A. Hiersche

DEFINITION

- Alveolar clefts are present in patients with orofacial clefts that involve the maxillary alveolar ridge.
 - The defect can range from a simple alveolar notch to a complete cleft that involves the alveolus, maxilla, and inferior piriform rim.
- Secondary alveolar bone grafting, as originally described by Boyne and Sands,¹ is the final step in closure of the orofacial cleft. This procedure closes the nasoalveolar fistula, unites the maxillary arch in preparation for definitive orthodontic treatment, creates support for the affected nasal structures, and provides alveolar bone for the support of the lateral incisor (if present), the canine, and surrounding dental structures.
- Alveolar bone grafting is most often performed by utilizing autogenous bone from the iliac crest, which remains the standard.
 - Other donor sites include the cranium, tibia, and mandibular symphysis.^{2–4}
 - The use of allogenic bone and bone morphogenetic protein (BMP) has also been reported.^{5,6}

ANATOMY

- An alveolar cleft is a three-dimensional cleft in the maxilla most often extending from the piriform rim to the alveolar margin.
 - The bony cleft is shaped as an inverted pyramid with its base at the piriform rim and its pinnacle at the alveolar margin (**FIG 1**).
- Distal to the cleft, the alveolus may be hypoplastic, and the lateral maxillary

segment may be displaced posteriorly and collapsed medially.

- The alveolus/piriform rim acts as the “foundation” for the overlying soft tissue of the lip and nasal tip.
- Alveolar clefting and displacement of the lateral maxillary segment may thus result in displacement and distortion of the lip, nasal sill, and alar base.
- Dental anatomy adjacent to the cleft is often anomalous, demonstrating abnormalities in the position, shape, and presence of the canine and lateral incisor. Likewise, abnormalities in dental structure (eg, enamel hypoplasia, root abnormalities) and in dental eruption patterns are often noted.⁷

PATHOGENESIS

- The face is formed through the fusion of five facial prominences that develop and fuse in weeks 6 to 8 of development. These facial prominences are the midline frontonasal prominence, the paired lateral nasal prominences, and the paired maxillary prominences.
- The frontonasal prominence (median nasal prominence) forms the forehead, nasal bridge, nasal tip, columella, philtrum and central upper lip, septum, and premaxilla (primary palate).
- The paired lateral nasal prominences form the alae of the nose.
- The paired maxillary prominences form portions of the cheek, the lateral components of the upper lip, the maxilla, and the lateral palatal shelves (secondary palate).
- In normal development, the primary palate, which receives its blood supply via the sphenopalatine artery from the septum, fuses with the bilateral palatal shelves to complete the development of the palate.
- In clefts involving the alveolus, the primary palate and secondary palate fail to fuse at the alveolus, maintaining a connection between the oral and nasal cavities.

FIG 1 • A,B. Cone-beam CT demonstrating the pyramidal defect of the alveolar cleft.

- The etiology of cleft lip and palate is multifactorial with both genetic and environmental factors contributing to the development of orofacial clefts.
- To be etiologic, environmental factors must affect the fetus between weeks 6 and 8 of development, as this is the critical time for development of the primary palate.
- Medications that have been implicated in the development of a cleft lip and palate include anticonvulsants, folate antagonists, benzodiazepines, corticosteroids, and beta-blockers.
- Certain maternal factors have been implicated in the development of cleft lip and palate, including smoking, excessive alcohol consumption, and obesity.
- Maternal health conditions may also contribute, including diabetes and maternal fever.
- Lastly, a family history of cleft lip and palate is one of the strongest risk factors for the development of a cleft lip or palate, implicating a complex genetic component.

NATURAL HISTORY

- The need for repair of the alveolar cleft is generally accepted; however, timing of alveolar bone grafting remains controversial.
 - Primary alveolar bone grafting is not practiced at most centers in light of evidence that it has a negative influence on maxillary growth.^{8,9}
 - The remainder of this chapter is pertinent to secondary alveolar bone grafting.
- In the absence of primary alveolar bone grafting or gingivoperiosteoplasty, the

alveolar cleft remains as a persistent nasoalveolar fistula following closure of the lip and palate.

- The persistent fistula allows regurgitation of oral contents into the nose and passage of nasal secretions into the oral cavity. Additionally, the cleft traps food products, reduces oral clearance, obstructs basic hygiene, and may contribute to periodontal disease and dental decay.
- Without alveolar bone grafting, patients may maintain a flat, depressed lip, nasal sill, and alar base secondary to inadequate bony support of the soft tissues overlying the deficient piriform rim. Likewise, inadequate bone stock may lead to dental loss due to insufficient periodontal support.
- The reconstructed alveolus and piriform rim support the overlying nasal structures.
- Following closure of the alveolar cleft, orthodontic canine substitution may be employed to camouflage the defect resulting from an absent lateral incisor. Alternatively, the graft may be used to support replacement of the absent lateral incisor through implant placement.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Regurgitation of liquids or solids into the nose through a persistent nasoalveolar fistula may be reported.
- Oral hygiene practices, regular dental evaluations, and current or prior orthodontic treatment must be documented and discussed in detail, as the proper coordination of dental and orthodontic care is important in ensuring optimal outcomes in secondary alveolar bone grafting.
- It is important to solicit the patient's surgical history as it pertains to any prior cleft lip or palate procedures, as well as prior surgical treatment of the alveolus, whether primary or secondary.
- Additional treatment for or the presence of additional oronasal fistulae should be assessed.
- On physical examination, the presence, location, stability, and morphology of the dentition adjacent to the cleft should be assessed, as well as noting overall oral hygiene, dental decay, and periodontal disease.
- Overall, arch form should be assessed, as orthodontic preparation of the arch through expansion is often necessary to place the alveolar segments in an optimal position for bone grafting.
- Evaluation for the presence of an additional oronasal fistula should be

performed, noting the prior method of palate repair.

IMAGING

- Panoramic and occlusal x-rays have been traditionally used to image the alveolar defect and to assess graft take postoperatively.
- When available, a cone-beam CT scan offers improved three-dimensional evaluation of the cleft area and the adjacent dentition.
 - It may be used to more accurately assess bone graft take by providing a high-resolution, three-dimensional image of the alveolus.

NONOPERATIVE MANAGEMENT

- Patients who are not candidates for or who decline alveolar bone grafting may be offered prosthetic habilitation of the cleft site.
- This can be achieved with a variety of fixed and removable devices for aesthetic replacement of the missing dentition and acrylic coverage of remaining fistulae.^{10,11}

SURGICAL MANAGEMENT

- Repair of the alveolar cleft is generally performed during the stage of mixed dentition, which ranges from 6 to 10 years of age.
 - Graft placement should be performed before eruption of the permanent canine (or lateral incisor, when present) adjacent to the cleft.
 - Imaging is performed to assess root formation of the canine or lateral incisor, and grafting is performed once approximately half of the root has developed.
 - Performing the surgery at this stage provides bony support for the tooth as it erupts, and eruption of the tooth through the bone graft supports retention of graft volume.
 - Delayed tooth eruption into the graft area may result in loss of alveolar height and bony support. Thus, the goal is to provide early bony support for tooth eruption while minimizing the time between grafting and eruption of the permanent canine or lateral incisor.
- The main steps in the procedure are as follows:
 - Development of soft tissue flaps to close the nasal floor, surface the buccal gingiva, and close any residual palatal fistulae
 - Approximation of the nasal and palatal flaps to line the periosteal pocket for the bone graft
 - Harvest of cancellous iliac crest bone graft

- Placement of the bone graft into the prepared pocket
- Approximation of the buccogingival flaps
- Placement of an intraoral splint, if necessary
- Closure of the iliac donor site in layers, including closure of the cartilaginous cap of the iliac crest
- Indications for surgical management: patent alveolar fistula, dental arch collapse, deficiency of the piriform rim, support of adjacent teeth, and completion of dental habilitation (orthodontics and prosthodontics)
- Contraindications to surgical management: noncompliance with preoperative orthodontic preparation and poor oral hygiene resulting in gingivitis or caries adjacent to the alveolar cleft

Preoperative Planning

- Panoramic and occlusal radiographs or cone-beam CT scan should be obtained to determine stage of root development and bony support of teeth immediately adjacent to the cleft.
- Physical examination is performed to assess the condition of soft tissues and dentition, arch form, and presence of oronasal fistulae.
- Dental/orthodontic consultation should be obtained to assess the patient's overall oral hygiene, readiness for bone grafting, and the need for dental extractions, restorations, and alignment prior to bone grafting.
- Orthodontic consultation should be obtained to determine the need for maxillary expansion to restore arch form and transverse width (**FIG 2**).
- Teeth that have erupted horizontally in such a way as to impede access to the surgical site or that are in traumatic occlusion should be repositioned with orthodontic devices using caution to avoid moving the roots of teeth into the cleft defect.
- Teeth that have erupted into the cleft site or primary teeth that will interfere with the soft tissue closure of the graft site should be extracted prior to alveolar bone grafting.

Positioning

- The patient is placed in the supine position.
- If an autologous bone graft from the iliac crest is to be harvested, the operative hip should have a small bump placed beneath it to assist in exposure for the graft harvest.

- A small shoulder roll and slight extension of the head will assist with exposure.
- A Dingman retractor may be utilized for exposure, placing the hooks on the upper lip for exposure of the alveolus and on the alveolar ridge for exposure of the anterior palate.

Approach

- Intraoral exposure of the cleft site is obtained through the elevation of buccogingival and, if necessary, palatal flaps.
- The donor site is approached through a 3-cm incision placed 2 cm posterior to the anterior superior iliac spine to avoid the lateral femoral cutaneous nerve.
- The incision should be placed slightly lateral to the most prominent portion of the iliac crest in order to avoid irritation from clothing postoperatively.

FIG 2 • Maxillary dental arch before **(A)** and after **(B)** orthodontic expansion.

TECHNIQUES

■ Alveolar Cleft Dissection

Preparation

- The oral splint should be fit prior to the procedure to ensure proper retention postoperatively.
- Slight extension of the neck is ideal for exposure, particularly if a palatal fistula is present and will require closure.

- Corneal protection is imperative for the duration of the procedure. The senior author's preference is to apply adhesive dressings over the eyes prior to skin preparation, but protection methods vary and are at the discretion of the surgeon.
- After skin preparation and draping, the oral cavity is rinsed with Peridex solution.
- A Dingman mouth gag is then used to provide exposure to the alveolus (**TECH FIG 1**).
 - The hooks are placed on the upper lip to provide retraction of the lip and exposure of the labial alveolus and dentition.
 - The cheek retractors should be used to retract the cheeks and stabilize the mouth gag.
- The alveolar and, if present, palatal fistulae should be examined closely at this time. Lacrimal probes may be used to interrogate the fistulae and define their extent.

TECH FIG 1 • Placement of the Dingman retractor for proper exposure.

Dissection of the Fistula

Video p2-c029

- The incisions are marked along both the lateral and medial aspects of the alveolar fistula. The incision is marked along the gingival margin extending from the cleft mesially no further than the midline.
 - Laterally, the incision begins at the lateral cleft margin and extends along the gingival margin.
 - Distal to the tooth adjacent to the cleft, the incision may be extended obliquely from the gingival margin, extended just above the attached gingiva, and then posteriorly to the position of the first molar.
 - At the first molar, a back cut can be made to facilitate advancement of the gingival flap (**TECH FIG 2A**).
- The fistula and surrounding labial/palatal mucosa are injected with a 1:200 000 epinephrine solution for hemostasis.
 - As the mucosa is highly vascular, it is traditionally recommended that the surgeon wait 7 to 10 minutes between injection and incision to allow for vasoconstriction. However, recent studies indicate that waiting 26 minutes, when clinically feasible, may provide optimal vasoconstriction.¹²
- The incisions are then made at the gingival margin, avoiding injury to the papillae while dividing the periodontal ligament.
 - This dissection is extended onto the alveolus in a subperiosteal plane.
 - The incision proceeds around the cleft margin, a maneuver that may be facilitated by use of an angled crescent knife (**TECH FIG 2B**).
 - The lateral and medial buccogingival flaps are then elevated to expose the bony cleft margin to the piriform rim (**TECH FIG 2C**).
 - The periosteum at the base of the lateral flap is then scored in order to

facilitate its mobilization (**TECH FIG 2D**).

Dissection Within the Cleft

- Once the labial margin of the fistula has been dissected and the buccogingival flaps elevated, attention can be turned to dissection of the soft tissues within the cleft.
 - Subperiosteal dissection should be continued along the medial and lateral cleft margins. This dissection should be performed/extended from the piriform rim to the alveolar margin and to the posterior extent of the fistula.
 - After elevation, the mucosa lining the lateral and medial aspects of the cleft can then be incised to create the nasal and oral flaps.
 - Sharp iris scissors can be used to incise the flaps posteriorly along the floor of the cleft (**TECH FIG 3**).
 - This dissection should be extended posteriorly just beyond the posterior extent of any residual anterior palatal fistula.
- If a palatal fistula is present, the palatal mucosa is elevated from the palatal gingival margin.
 - Elevate the previously incised oral mucosal flaps from within the cleft in continuity with the palatal mucosa.
 - Often, wide dissection of the palatal flaps is necessary for visualization and closure of the palatal fistula.

TECH FIG 2 • **A.** Markings demonstrating the extent of the surgical incisions. **B.** The incision is extended to the apex of the labial cleft. **C.** Exposure of the maxilla on the lateral cleft up to the level of the defect in the piriform rim. **D.** Scoring the periosteum of the lateral flap to facilitate medial transposition of the flap and fistula closure.

TECH FIG 3 • **A.** Elevation of the mucosa within the cleft on the medial side of the cleft. **B.** Division of the mucosal flaps within the cleft for creation of the nasal floor of the alveolus.

Closure

- Closure of the nasal lining should be performed prior to closure of the palatal defect as the nasal closure is often the most technically demanding portion of the procedure and is facilitated by optimal exposure.
 - The senior author prefers use of a 5-0 Vicryl suture on a P-2 needle for closure of the nasal lining.
 - Regardless of the needle selected, a small radius of curvature will facilitate manipulation of the needle within the confined space of the alveolar cleft.
- Closure of the palatal fistula is then performed. Use of horizontal mattress sutures optimizes healing through eversion of the edges of the stiff palatal mucosa.
- If palatal flaps have been elevated, the palatal mucosa can be resuspended and circumdental sutures secured above the cingulum.

- The space created for the bone graft can now be visualized in three dimensions (**TECH FIG 4A**; see **FIG 1**).
- The cancellous bone graft is packed into the alveolar cleft from the piriform rim to the alveolar margin (**TECH FIG 4B**).
- The gingival flaps are then sutured to cover the labial fistula.
 - The lateral and medial flaps are sutured to one another with resorbable everting horizontal mattress sutures.
 - The inferior margins of the gingival flaps are sutured to the palatal flaps with simple, interdental sutures (**TECH FIG 4C**).
- If a splint is to be used, it should be secured prior to awakening the patient.

TECH FIG 4 • **A.** The alveolar cleft can be visualized with nasal and palatal closure. **B.** Demonstrating placement of the bone graft within the cleft. **C.** Final closure of the cleft after placement of the bone graft.

■ Iliac Crest Bone Graft Harvest

- The incision should be marked prior to the surgical prep.
 - The anterior superior iliac spine (ASIS) is identified and marked.
 - The distal aspect of the incision is placed 2 cm proximal to the ASIS to protect the lateral femoral cutaneous nerve (**TECH FIG 5**).
 - The incision should be designed by rolling the lateral skin medially over the iliac crest. This maneuver allows the surgeon to identify a point lateral to the iliac crest that can be easily positioned over the iliac crest for surgical dissection while keeping the incision off of the bony prominence.
 - Designing the incision lateral to the iliac crest will avoid a painful scar over the iliac crest that may be irritated by clothing.
 - The incision should measure approximately 3 cm in length.

TECH FIG 5 • Design of the incision for harvest of the iliac crest bone graft.

- The skin is infiltrated with 1% lidocaine with epinephrine prior to surgical preparation in order to facilitate hemostasis.
- After allowing adequate time for vasoconstriction, the incision is extended sharply to the iliac crest.
 - A self-retaining retractor may be used to assist with exposure.
 - The iliac crest should be identified at the junction of the insertion of the external oblique musculature and the origin of the tensor fasciae latae.
 - Entering the iliac crest through the junction will eliminate an incision

through deep fascia and minimize postoperative pain.

- The lateral and medial surfaces of the iliac wing are palpated to identify the angle of the iliac wing.
- An osteotome is then used to open the cartilaginous cap in line with that angle.
- The senior author prefers to make a single linear opening in the middle of the cartilage cap that parallels the lateral and medial surfaces of the iliac wing.
- This linear opening in the cartilage cap may be widened with a small curette to allow access to the cancellous bone, without elevating the cartilage cap.
- A small curette is then used to harvest the cancellous bone graft; avoid perforating the lateral or medial cortices of the ileum.
- When sufficient cancellous bone has been harvested, the wound should be irrigated and 0.25% Marcaine infiltrated along the periosteum and instilled into the medullary cavity for analgesia.
- A resorbable suture may be used to close the cartilaginous cap of the ileum.
- The incision is then closed in layers, and a sterile dressing applied.

PEARLS AND PITFALLS

Physical findings	■ Closure of residual oronasal fistulae must be performed prior to or at the time of alveolar bone grafting. ■ Evaluation and optimization of oral hygiene prior to alveolar grafting is essential to successful bone graft surgery.
Dental/orthodontic preparation	■ Orthodontic evaluation and preparation with appropriate restorations, extractions, and palatal expansion is essential.
Technique	■ Watertight closure of the nasal floor is essential for bone graft take. ■ Wide exposure of the cleft allows adequate visualization of the nasal floor and access to the cleft for grafting. ■ Sufficient bone graft should be harvested to allow the alveolar cleft to be filled from the piriform rim to the alveolar margin.

Postoperative care

- Tension on flap closure should be minimal and may be assisted by scoring the periosteum at the base of the lateral buccogingival flap.
- A splint should be utilized in patients with uncorrected traumatic occlusion and in those who have undergone transverse maxillary expansion.
- A soft diet should be maintained for 3 wk postoperatively to minimize the risk of traumatic injury to the surgical site.
- Contact sports should be avoided for 4 wk following surgery if the iliac crest is used as the donor site.

POSTOPERATIVE CARE

- An intraoral splint is used to maintain palatal expansion if orthodontic appliances are removed prior to surgery. The splint will also relieve traumatic occlusion, potential injury to the surgical site, and impaction of food.
- A liquid diet is advocated for the first 24 hours, and a soft diet is appropriate for 3 weeks postoperatively.
- The patient maintains the splint in position while eating and only removes the splint to perform an oral rinse after each meal.
- At 3 weeks, the patient may remove the splint and begin brushing gently.
- The patient may bear weight as tolerated on the donor hip immediately but should refrain from contact sports for 4 weeks.

OUTCOMES

- Outcomes assessment includes clinical evaluation and radiographic imaging of the alveolar bone graft.
- Clinically, the presence of an alveolar or palatal fistula is a primary outcome determining surgical efficacy of closure of the fistulae.
 - It may be necessary to use a fine dental probe to assess for small fistulae.
 - In the absence of an overt fistula, clinical symptoms of liquid regurgitation into the nose should alert the physician to the presence of a persistent or recurrent fistula.
- Dehiscence of the oral and/or nasal suture lines jeopardizes the viability of the alveolar bone graft.
- Radiographic evaluation of the alveolar bone graft is usually deferred until 6 months following bone grafting, so as to allow for bony regeneration across the alveolar cleft.

- The Bergland Scale Score serves as a radiographic gold standard for assessing alveolar bone graft take. The scale is a four-point scale that serves to assess the height of interdental bone as viewed on occlusal radiographs.¹³
- This scale may fail to adequately evaluate the presence of interdental bone as it is a two-dimensional analysis of the alveolar cleft. Occlusal radiographs fail to clearly demonstrate the overall quality of bone retention in the coronal plane.
- Recently, the Americleft Project has introduced a new assessment standard, the Standardized Way to Assess Grafts (SWAG).¹⁴ This is a six-point scale with scores of 0 to 1 indicating graft failure, 2 or 3 indicating a poor graft requiring regrafting, 4 or 5 indicating a successful graft that may require augmentation, and 6 a successful graft.
- Cone-beam computed tomography has emerged as a safe, rapid, and effective means of obtaining a three-dimensional evaluation of the graft site. While a scale using cone-beam CT has not been validated, studies have shown that scales using standard radiographs do not identify bone resorption in the buccopalatal dimension.¹⁵
- Resorption of approximately 50% in this transverse dimension has been reported within the first year following bone grafting.¹⁶

COMPLICATIONS

- Infection
- Bleeding
- Partial or complete graft loss
- Recurrence of the oronasal fistula
- Tooth damage or loss
- Hip pain
- Fracture of the iliac wing
- Injury to intra-abdominal contents
- Paresthesia of the lateral femoral cutaneous nerve
- Hypertrophic scar
- Scar irritation with clothing if the incision is placed directly over the iliac crest
- Anesthetic complications

30 Surgical Management of Facial Clefts

CHAPTER

David C. Matthews, Samer Abouzeid, and Edward W. Kubek

DEFINITION

- Craniofacial clefts are rare congenital anomalies of facial development involving the facial bones, overlying soft tissue, and temporomandibular joint.
- Facial clefts are classified by their involvement of the orbitomaxillary anatomy according to the Tessier classification.¹
- Each craniofacial cleft is associated with characteristic, yet highly variable, bony and soft tissue changes ranging from mild hypoplasia to total agenesis.
- Facial clefts and labiopalatine clefts are separate entities with key differences in surgical management and incidence.
- The extreme variation of facial cleft anatomy mandates a unique surgical approach for every patient.²

ANATOMY

- Dr. Paul Tessier published his 0 to 14 organizational system in 1976 (**FIG 1**).¹
 - Because of its clinical utility and relative simplicity, Tessier's nominal system continues to be used widely.
- For purposes of nomenclature, the palpebral fissure/orbit separates lower facial clefts from their cranial extensions.
 - When they occur together, the numerology of the lower facial cleft plus its cranial extension always equals 14.
- Tessier's 0 to 14 system is based on clinical experience, not embryologic study (Table 1).

PATHOGENESIS

- The etiology of facial clefting is incompletely understood but likely involves

both genetic and epigenetic factors.²

- Abnormalities or premature resolution of the stapedia artery during fetal development is known to cause facial clefting.
- The severity of the deformity relates to the timing of stapedia artery regression in utero.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In facial clefts, the bone and soft tissue are rarely affected to the same degree.

FIG 1 • Tessier classification of clefts. **A.** Paths of various clefts on the face. **B.** Location of the clefts on the facial skeleton. (From Tessier P. Anatomical Classification of facial, craniofacial and lateral-facial clefts. *J Maxillofac Surg.* 1976;4:69-92.)

Table 1 Tessier System of Cleft Identification

Tessier Cleft No.	Description	Cranial Extension Equivalent Cleft No.	Bony Abnormalities	Effects on Soft Tissue and Appearance

0	Median craniofacial dysraphia	14	• Similar to labiopalatine cleft but located at the midline (teeth fall into cleft)² • Wide nasal bones with enlargement of the sphenoid and ethmoid sinuses • Duplication of the crista galli • Cleft of the primary and secondary palate • Maxilla lacking vertical height • Hypertelorism	• Broad philtral columns • Duplication of midline nasal structures, including the nasal spine and septum • Bifid nose and labial frenulum
1	Paramedian craniofacial cleft	13	• Traverses nasal bone and maxilla into the pyriform • Results in an anterior open bite • Effect on the ethmoids results in orbital hypertelorism	• Traverses the dome of the alar cartilage, giving a notched appearance • Widening of the columella and nasal tip
2	Paramedian craniofacial cleft	12	• Traverses the	• Traverses

			lateral mass of the ethmoid with malformation of ethmoidal labyrinth • Localization on the frontal bone (corresponding with no. 12 cleft) is anatomically imprecise • Flat glabella with enlarged frontal sinus	between the nasal tip and the base of the alar cartilage • Associated with cleft lip • Ipsilateral absence of the lacrimal apparatus • Hypertelorism
3	Medial orbitomaxillary cleft or paranasal cleft	11	• The oblique course of the cleft traverses the lacrimal groove • Frontal process of maxilla is often absent • Medial wall of maxillary sinus is often absent	• Traverses the alar base, nasolabial fold and alveolus, causing a cleft lip

4	Median orbitomaxillary cleft	10	• Traverses infraorbital rim and floor medial to infraorbital nerve • Traverses the maxillary sinus leading to sinus exstrophy • Associated	• Vertically traverses the lacrimal segment of the lower lid • Cleft lip is located between philtral crest and commissure

			alveolar cleft appears similar to the typical alveolar cleft	
5	Lateral orbitomaxillary cleft	9	• Traverses the infraorbital rim lateral to infraorbital foramen • Results in an alveolar cleft of the premolar region	• Traverses the medial third of the lower lid • Soft tissue groove is visible on the cheek from lower lid to lateral lip near the commissure
6	Intermaxillozygomatic cleft	8	• Located between the maxilla and zygoma; opens into the inferior orbital fissure	• Laterally located coloboma of the lower lid
7	Temporozygomatic cleft	7	• Absent or atrophic zygomatic arch • Shortening of the ascending ramus and	• Absence of the coronoid process accompanied by ipsilateral absence of the temporalis muscle

			reduced height of the maxilla • Absence of the coronoid and mandibular condyle is common	• Microtia and pretragal enchondroma • Macrostomia
8	Frontozygomatic cleft	6	• When the malar portion of zygoma is absent, the greater wing of sphenoid becomes the lateral-most border of the orbit	• A true cleft of the lateral canthus is associated with Goldenhar syndrome
9	Superolateral orbital cleft	5	• Traverses the superolateral orbit	• Traverses the lateral third of the upper lid
10	Central superior orbital cleft	4	• Traverses medial third of supraorbital rim and orbital roof • Lateral to the supraorbital nerve	• Coloboma of the upper lid can be severe (clinical ablepharia)
11	Superomedial orbital	3	• Traverses the	• Coloboma of

	cleft		ethmoid or supraorbital rim lateral to the ethmoid	the medial third of the upper lid • Cleft traverse the medial brow
12	Paramedian craniofacial cleft	2	• Traverses frontal bone and lateral mass of the ethmoid • Enlargement of the frontal sinus	• Coloboma at the root of the eyebrow
13	Paramedian craniofacial cleft	1	• Traverses the frontal bone and olfactory groove of the cribriform plate • Absence of the ipsilateral nasal bone	• Cleft is medial to the eyebrow • Associated with encephalocel and hypertelorism
14	Median craniofacial dysraphia	0	• As with cleft no. 0, often see duplication or widening of midline structures • Bifid crista galli and ethmoid plate may be present • Rotation of the sphenoid wings causes	• Widening or duplication of midline anatomy, including frontonasal encephalocel hypertelorism and telecanthus

			attenuation of the middle cranial fossa	
--	--	--	---	--

FIG 2 • Patient with a Tessier no. 5 cleft on the right side of the face and no. 3 cleft on the left.

- From midline to the infraorbital foramen, the physical deformity and morbidity of the soft tissue defects are more evident compared to the bony defects (**FIG 2**).

- From the infraorbital foramen to the temporal bone, bony defects are more clinically severe with the exception of changes to the external ear.
- The spectrum of soft tissue deficiency of facial clefts varies more widely than standard labiopalatine clefts.

IMAGING

- A maxillofacial CT scan helps define the anatomy of the orbit and maxilla.
- The orbital floor defect and position of the zygoma are key features to examine.
- Evaluate for comorbid conditions (eg, cardiopulmonary anomalies).

DIFFERENTIAL DIAGNOSIS

- Hypertelorism
- Microphthalmias
- Orbital dystopias
- Treacher Collins syndrome
- Goldenhar syndrome
- Hemifacial microsomia are all associated with facial clefting

NONOPERATIVE MANAGEMENT

- Management is tailored to each individual patient and guided by principles over protocols.
- The older the patient at the time of bone grafting, the better.
- The one exception is if the cornea is compromised. Earlier surgery is mandatory in this case.
- The eye should always be hydrated if exposure is suspected due to facial clefting.

SURGICAL MANAGEMENT

- This chapter focuses on the management of Tessier no. 3, 4, and 5 clefts.
- Tessier clefts other than 0/14, 0/13, and 2/13 require a large amount of bone.
 - Otherwise, the bone resorbs and has to be regrafted several times because it does not grow with the patient.
- There can be major soft tissue defects with minor bone defects and vice versa.
- Marked individuality is the rule.
- Careful attention to eyelid colobomas is mandatory.
- There may be a future for cadaver grafts for initial surgeries because the bone

graft sources are limited in children.

- The ideal time for grafting is after facial growth is nearing completion. At this time, grafts do not resorb to the same extent.

Preoperative Planning

- Ophthalmologic exam is documented preoperatively.
- Goals of surgical management of Tessier clefts no. 3, 4, and 5^{2,3}:
 - Protect the cornea from exposure keratopathy and blindness with early repair of colobomas (upper greater than lower lid).
 - Early repair of soft tissue deformities with rotation advancement and avoidance of Z-plasty incisions that violate subunit principles.⁴
 - Address anatomic structures for optimal symmetry (lip, nasal ala, alveolus, inferior orbit/globe, and medial canthus).
 - Plan incisions along subunit lines whenever possible.
 - Dissection and anatomic repositioning of facial musculature improves future animation and midface growth.⁴
 - Liberal use of secondary tissue expansion for wider clefts where medial subunit incision lines were not feasible initially.²
- As a general rule, 2 to 3 mm of overcorrection is required when suspending the medial canthus, adding bone to the inferior orbital rim, and dropping the cleft-side alar base are essential to durable results.⁴
- Split calvarial bone grafts can be obtained after 5 years of age.
- Orthodontic management of occlusion follows a timeline similar to labiopalatine clefts.

Positioning

- Supine with shoulder role to extend the neck
- The endotracheal tube is positioned at midline.
- The face and neck receive a sterile prep (Betadine); eyes are irrigated with balanced salt solution (BSS) and closed with ophthalmic ointment.
- The head is draped with the entire face in the field.

Approach

- The designs for skin incision must be tailored to the severity of soft tissue deficiency between the nasal ala and medial canthus. A simple Z-plasty approach is shown.

TECHNIQUES

■ Management of Tessier Cleft No. 3, 4, or 5

- The skin is incised along subunit lines medially (**TECH FIG 1A**).
- Incise the medial side of the cleft and then the lateral side. The subunits are the lip, nose, and then the cheek-nose junction.
- For soft tissue–only operations, facial muscles are reapproximated (nasalis, orbicularis oculi, and oris).
- For bony clefts, dissection is extended to the bony cleft margin (**TECH FIG 1B**).
- The bony margins are exposed with subperiosteal dissection.
 - Unlike labiopalatine clefts, our practice is to refresh the bone edges with a bur similar to the technique described by Tessier.
- The dimensions of autologous bone needed for harvest are measured and confirmed.
- Autologous bone (calvarial, iliac, tibial) is preferred over nonautologous bone, but in our experience, demineralized cadaveric bone substitutes are also useful.
- Bone grafts are placed to bridge the cleft and approximate normal anatomic contours while anticipating a significant degree of graft resorption.
- Overcorrecting natural anatomic contour is recommended to the maximal extent that soft tissue coverage allows.
- To that end, wide periosteal elevation of soft tissue, as advocated by Tessier (lateral to the molars on each side), is allowed.
- To gain additional soft tissue mobility for wide or bilateral facial clefts, Tessier advised a back-cut in the periosteum along the lateral maxillary buttress.
- The bone grafts are fixed as necessary using lag screws, 2-0 Vicryl, or are simply held in place by the soft tissue envelope and globe (**TECH FIG 1C**).

TECH FIG 1 • A. To access the underlying bony defect, incisions are made along the border of the cleft, at the junction of skin and mucosa. **B.** Once incisions are made, the body margins of the cleft are exposed, and cancellous bone is used to fill the entire defect. **C.** In addition to cancellous bone filling, cortical bone should be used along the alveolar edge and the orbital edge and then fixed into position with screws.

- Medullary (cancellous) bone is used like plaster to fill gaps between cortical bone grafts and should lay over the interface of graft and maxilla.
- Lower eyelid support is achieved with bone grafts to the orbital rim and inferiorly based frontonasal flaps.
- Bone grafts to the orbital rim should exceed the normal height by 2 to 3 mm

anticipating partial resorption.

- Medial canthopexy is best done using a transnasal wire technique.
- The lateral canthus is suspended vertically with anchoring sutures to the orbital periosteum superiorly. Lateral traction places the medial canthopexy at risk.
- Proper bone graft volume necessitates moderate tension of the soft tissue at the time of closure.
- Meticulous layered closure of periosteum, mucosa, muscle, and skin is performed top-down to align lower lids, malar soft tissue, alar bases, and involved lip segments. Approximating the orbital to malar periosteum is essential for malar suspension.
- A tarsorrhaphy is recommended.
- If parietal bone is harvested, a 7-French closed suction drain is placed and removed at 24 to 48 hours.
- The goals of revision at the time of secondary surgery are to conceal incisions along medial subunit lines.
 - A combination of planning far into the future at the time of initial surgery, nasalis muscle dissection and reinsertion, and tissue expansion to allow medialization of scars is essential to achieve optimal surgical and psychosocial outcomes.^{2,4}

PEARLS AND PITFALLS

Physical findings

- Soft tissue and bone deformities often do not correspond to each other.
- Medial to the infraorbital nerve, the soft tissue deformities predominate.
- Lateral to the infraorbital nerve, bony deformities predominate.

Technique

- Z-plasty incisions that violate subunit principles will not improve with time.²
- For wide clefts where Z-plasties are used for initial closure, future use of tissue expansion to reposition scars along medial subunit lines markedly improves appearance.²
- The orbital rim bone graft is essential for lower eyelid support and correction of dystopia.

- Raising the rim and globe 2–3 mm (on-table) compared to the noncleft side is advised.
- We recommend periosteal coverage of bone grafts whenever possible.
- Calvarial bone is preferred over rib grafts.
- Overcorrecting the alignment of key structures by 2–3 mm is advised.^{2–4}
- Upper eyelid colobomas pose a greater risk to vision loss and should be corrected early.²

Postoperative

- Eye ointment should always be used to protect the eye.
- Repeat bone grafting may be required.

- For more severe deficiencies, an inferiorly based paramedian frontonasal flap can be designed to rotate 90 degrees toward the facial cleft to provide exposure and additional soft tissue between nasal ala and medial canthus (this maneuver helps to lengthen the nose and support the lower lid).
- Anatomic structures along the facial cleft margins are often hypoplastic or absent.
- A Doppler probe can be used to assess and preserve the ipsilateral angular artery. If the angular artery is absent, collateral flow from the contralateral system will perfuse an inferiorly based frontonasal flap.
- The lacrimal system is absent or nonfunctional in most Tessier cleft number 3 cases. If present, the anatomy is defined using probes and a lacrimal duct stent is placed.
- The insertion and function of muscles located between the cleft and nasal midline (nasalis, levator labii superioris, orbicularis oris, and orbicularis oculi) are often abnormal.

POSTOPERATIVE CARE

- Eye ointment should be used to keep the eye lubricated.
- Chlorhexidine mouth wash should be used if patient is old enough to cooperate; if not, water gargle after each meal is advised.
- After healing, a light massage to the eyelid to soften scar tissue should be applied.

OUTCOMES

- Secondary bone grafts may be required due to lack of growth in the area of the graft.

- Bone resorption and/or loss should be anticipated.

COMPLICATIONS

- Bone infection, especially involving areas of the bony reconstruction where it will take the longest for the avascular bone graft to be replaced with new vascular bone
- Wound dehiscence
- Bone resorption
- Skin retraction (especially involving the lower eyelid)

CHAPTER Gingivoperiosteoplasty

Mark C. Martin

DEFINITION

- Involvement of the alveolus in an oral cleft requires treatment to establish bony continuity of the divided maxilla.
- Closure of the alveolar cleft has many positive effects including preventing nasal regurgitation of liquids, preservation of crestal bone height necessary for periodontal health, allowing safe orthodontic movement of teeth, and improving stability of the maxillary arch against relapse after occlusal correction.
- The ideal age for alveolar cleft closure is controversial.^{1–4}
- Gingivoperiosteoplasty (GPOP) refers to repair of the alveolar cleft without bone grafting with the intention of promoting osteogenic bridging of the cleft by surgically creating a closed space across the alveolar cleft lined by mucoperiosteal flaps.

ANATOMY

- The alveolar cleft ranges from a minor notch to a complete cleft of the primary and secondary palate.
- The cleft presents as a variable gap that involves displacement, deformity, and hypoplasia.
- The cleft margin on the major segment flares anteriorly and deviates toward the noncleft side, and the alveolar stump curves cranially as the growth force of the vomerine septum lacks a restraining connection to the lesser maxillary segment (**FIG 1A**).
- The cleft margin of the minor segment is positioned posteriorly, and its alveolar stump curves in a cranial direction from the frontal view as it

approaches the cleft (**FIG 1**).

- The maxillary primary central incisors erupt at a variable age (usually between 6 and 12 months) and depending on the age of presentation and the surgeon's preferred timing for GPOP, these teeth may or may not be present at the time of surgery.
- The primary lateral incisor erupts between 12 and 18 months and on the cleft side is commonly hypoplastic or may be absent or accompanied by supernumerary teeth.
- Natal teeth may go unnoticed early in life in the setting of the cleft and be present high in the nose, which can affect the design of mucoperiosteal flaps.
- The abnormal anatomy of the lateral cleft must be recognized as failure to develop different tissue types with heterotopic placement of existing tissues; choosing nonosteogenic membranes to line the alveolus repair may diminish the chance of adequate bone formation (**FIG 1B-D**).
- Synergistic with correct lining of the GPOP, the use of a medial nasal lining flap to resurface a lateral vestibular releasing incision between vestibular skin (vibrissae) and vestibular mucosa (hairless) allows correction of alar base position without using nonanatomic flaps.
- The anatomy of the medial cleft is difficult to visualize due to the three-dimensional deformity (**FIG 1E-G**).
- Dislocation of the caudal septum into the noncleft nasal floor and the cranial inclination of the medial stump of the alveolus creates an acute angle between the septal mucoperichondrium and nasal floor mucoperiosteum, which can be challenging to dissect and mobilize.
- By lifting the medial nasal lining flap in continuity with the septal mucoperichondrium and subsequently correcting the caudal septum in the midline, the medial nasal lining flap can be used for tension-free reconstruction of the nasal floor, as well as to line the vestibular release with thin supple tissue (**FIG 2**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Age of patient at presentation is important.
 - Early institution of nasoalveolar molding (NAM) is thought to have more lasting effects on nasal cartilages due to the presence of maternal hormones.⁵
 - Older children are more likely to disturb the appliance creating compliance difficulties.

- An alveolar cleft with alveolar segments in apposition may not benefit from NAM but should be monitored for unfavorable changes in position (increased gap) of the maxillary segments that can occur with oral-digital habits or feeding behaviors.
- An isolated cleft of the lip (primary palate) may benefit from the nasal molding effects of NAM, but the change at the alveolus will be limited by the rigidity imparted by bony continuity of the secondary palate.
- Infants with medical comorbidities will often tolerate NAM therapy, but individualized attention to the appliance's effect on feeding and weight gain is indicated.

IMAGING

- Imaging in the setting of isolated cleft lip and palate is not normally obtained before GPOP, but may be indicated to evaluate more extensive craniofacial clefts.
- Imaging to assess results of GPOP is not standardized and may involve a variety of modalities.
- Plain occlusal radiographs are commonly used to assess alveolar bone formation in young patients (primary and early mixed dentition) and periapical and/or panoramic radiographs in older patients (late mixed and permanent dentition).
- Cone-beam computed tomography (CBCT) is increasingly used and provides more detailed information than plain films regarding the adequacy of alveolar bone; the clinical utility of CBCT use is still under evaluation.

FIG 1 • A. The cleft alveolus deformity. The columellar base is displaced toward the noncleft side (*yellow arrow*). The greater segment alveolus stump is flared anteriorly (*red arrow*). The alar base on the cleft side is displaced posteriorly through its relationship to the pyriform rim (*blue arrow*). **B.** Lateral cleft anatomy. **C.** Gingival mucoperiosteum shaded *green*, labial mucosa shaded *orange*, vestibular skin with vibrissae shaded *blue*, vestibular mucosa *pink*, and hairless shaded *yellow*. **D.** *Yellow* incision plan including vestibular release between vestibular skin and vestibular mucosa to achieve medial nasal lining flap during closure. **E.** Medial cleft anatomy. **F.** Gingival mucoperiosteum

shaded *green*, labial mucosa shaded *orange*, vestibular skin with vibrissae fixed to medial crus shaded *blue*, mobile vestibular mucosa of membranous septum and nasal floor mucoperiosteum shaded *pink*, and hairless shaded *yellow*. **G.** Incision plan including medial nasal floor mucoperiosteal lining flap for nasal floor repair and lining of lateral vestibular back cut.

NONOPERATIVE MANAGEMENT

- There is no dispute that alveolar clefts benefit from repair; however, the timing and techniques for repair remain controversial.^{1–4}
- If GPOP is not done in infancy by design, or if it has been done unsuccessfully, secondary alveolar cleft repair with autologous bone grafting (most commonly with cancellous iliac crest bone) is a well-established procedure with a high success rate.⁶

SURGICAL MANAGEMENT

- GPOP in infancy is technically challenging and reported outcomes vary widely among authors.^{1–3,6–8}
- Some authors have reported an increase in midface growth deficiency, whereas others have not.^{2,4}
- A surgeon's technique has been shown to be an important determinant of facial growth after repair of oral clefts in general.
- Modern authors have demonstrated useful bone filling of the alveolar cleft from 73% to 100% depending on the specific technique and protocol.^{1,6}
- Even in patients who do not form adequate bone after GPOP, it has been reported that subsequent successful standard mixed dentition bone grafting is technically easier than in those not having undergone GPOP.⁶
- Successful GPOP eliminates one operation at school age and the need to use a painful distant donor site (most commonly the iliac crest in North America).
- GPOP is often preceded by NAM, which requires a skilled dental professional, significant time commitment from caregivers, may be costly, and can be ineffective in the setting of noncompliance.⁹

FIG 2 • A. Infant skull schematic showing caudal septal dislocation into noncleft nasal floor with *dark pink* nasal lining and *light pink* palate mucoperiosteum. **B.** Midline correction of the caudal septum allows lateral movement of the in-continuity medial nasal floor lining flap in concert with palatal mucoperiosteal repair.

- GPOP is most often performed at the time of cleft lip and nasal repair in North America either after NAM or in the setting of a pre-existing narrow cleft gap.
- Alternatively, mucoperiosteal repair of the alveolus can also be highly successful when performed at the time of palate repair, after muscle forces of the repaired lip mold the palatal segments into proximity.^{1,10}

Preoperative Planning

- Children with cleft lip and palate should be evaluated before surgery by a multidisciplinary team including the cleft surgeon, pediatrician, medical geneticist, otolaryngologist, pediatric dentist, speech and language pathologist, and social worker.
- Children with complete cleft lip and palate with an alveolar gap and/or significant nasal deformity benefit from NAM by a pediatric dentist or orthodontist with training and experience in the technique.
- The purpose of NAM is to gradually approximate the alveolar segments and to mold the nasal deformity in order to allow GPOP with minimal dissection and to facilitate cleft lip and nasal repair (**FIG 3**).
- Patients should be evaluated and treated by a trained pediatric anesthesiologist.

Positioning

- An oral Ring-Adair-Elwyn (RAE) tube is used and is secured in the midline.
- A short “mesentery” of tape allows use of a Dingman retractor without pinching the lower lip (**FIG 3B**).
- The infant is treated in the supine position using a soft headrest with mild neck extension and routine warming measures.
- The eyes are irrigated with balanced salt solution and protected with skin tape.

Approach

- Skoog reported a technique using wide undermining of the maxilla and periosteal flaps with Surgicel implantation in an attempt to promote bone formation at the alveolar cleft without bone graft.
- Skoog’s technique utilizing periosteal flaps has been generally abandoned due to reports of midface growth inhibition and poor bone formation.¹¹

FIG 3 • A. A wide cleft alveolus gap at initial presentation. **B.** After nasoalveolar molding with abutted alveolar segments.

- Millard reported a protocol involving a pin-retained appliance for maxillary segment positioning followed by GOP with small flaps.³
- Concerns about midface growth inhibition, possibly related to strong forces generated by the screw-activated facial orthopedic appliances, limit the current use of protocols relying on active pin-retained appliances.

- Smith et al. suggested an anatomic repair of the primary palate with mucoperiosteal flaps after physiologic alveolus molding occurred following initial nasolabial and soft palate repair, but reported no long-term outcomes.¹⁰
- Meazzini et al. used a similar protocol to that suggested by Smith et al. and reported a 100% success in avoiding secondary bone grafting.¹
- Wood et al. reported that a Millard-type GPOP after NAM did not result in early midface growth inhibition.⁴

TECHNIQUES

■ Markings and Incisions

- The plan for the cleft lip repair is marked per the surgeons' preferred technique.
- The alveolar cleft is inspected, and local anesthetic with epinephrine is injected along the gingival margins, palatal mucoperiosteum, nasal septum, and nasal floor (**TECH FIG 1A**).
- Incisions are made on the crest of the alveolus, mesial and distal to the cleft at the junction of gingival mucoperiosteum and palatal mucoperiosteum (**TECH FIG 1B,C**).
- Incisions are then made on the palatal surface along the margins of the cleft at the junction where the *deep red* nasal floor lining meets the *light pink* palatal mucoperiosteum.
- As part of the concurrent lip repair, the mobile labial mucosa is incised from the nasal vestibular mucosa on the lateral segment and the mobile mucosa of the membranous septum on the medial segment (**TECH FIG 1B**).
- The alveolar ridge incision between gingival and palatal mucoperiosteum converges with the incision between labial mucosa and vestibular mucosa at the entrance to the floor of the nose (**TECH FIG 1C**).

TECH FIG 1 • **A.** Frontal view of an infant with complete cleft lip and palate. **B.** Greater segment incisions between gingival and palatal mucoperiosteum on the crest of the alveolus and diverging at the nasal floor to define the medial nasal floor lining flap. **C.** Lesser segment incision between gingival and palatal mucoperiosteum along with vestibular release incision between vestibular skin and vestibular mucosa.

■ Flap Elevation

- The lateral segment gingivoperiosteal flap is elevated gently with a fine periosteal elevator.
 - Dissection should proceed mesial to distal and caudal to cranial starting at the crest of the alveolus and proceeding up the maxilla.
 - The teeth in the lateral segment are typically unerupted at the usual time for GPOP, and it is important to be gentle with dissection here as *forceful dissection directed from cranial to caudal has the potential to avulse unerupted teeth.*
- Dissection at the crest of the alveolar ridge should be completed sharply with scissors or scalpel to leave the tooth bud intact and not expose the crown.
- A lateral segment palatal mucoperiosteal flap is gently elevated with a Freer elevator with similar precautions to avoid traction on teeth at the crest of the alveolus.
- The mucoperiosteum of the lateral nasal floor is carefully elevated with a periosteal elevator.

- Elevation of the gingival, palatal, and nasal floor mucoperiosteal flaps on the lateral segment is performed progressively, only up to the point where tension-free closure becomes possible.
- On the medial segment, the gingivoperiosteal flap is elevated distal to mesial with a periosteal elevator in a subperiosteal plane, except at the crest of the alveolus where sharp dissection with scissors or scalpel frees the flap from the soft tissue of the tooth bud; the crown is not exposed if it has not yet erupted.
- A medial segment primary palatal mucoperiosteal flap is elevated with a Freer elevator.
- A medial segment nasal lining flap is elevated from the bone of the nasal floor, over the nasal surface of the primary palate up to the junction with the septum.
- The septal-nasal floor angle may be very acute, and gentle dissection is important to avoid flap perforation or injury to the caudal septum.

■ Repositioning of Elements

- At this point, contralateral subperichondrial dissection on the cartilaginous septum may proceed to allow midline relocation of the caudal septal cartilage.
 - The caudal septal cartilage is thin. Avoid damaging the septum during this step.
- Septal relocation to the midline has beneficial effects.
 - Subsequent primary rhinoplasty is easier when the septum is straight.
 - Bringing the septum to the midline lateralizes the medial nasal lining flap to allow tension-free nasal floor reconstruction (see **TECH FIG 1B**).
- The cleft deformity results in a posterior positioning of the bony nasal pyriform rim on the cleft side.
- The alar base and lateral crus of the lower lateral cartilage are tethered posteriorly and benefit from a vestibular releasing incision to allow repositioning of the alar base and lateral crus (see **TECH FIG 1C**).
- The medial nasal floor lining flap based on the cleft-side septal mucoperichondrium is used to span the nasal floor cleft and can also be used to line the defect resulting from a vestibular releasing incision (obviating the need for nonanatomic labial or inferior turbinate mucosal flaps; **TECH FIG**

2).

- At this point, the cleft-side alar dome can be easily repositioned without vestibular tightness or vestibular web formation.

TECH FIG 2 • Repaired palatal and gingival mucoperiosteal flaps with view of medial nasal floor lining flap inset into apex of vestibular releasing incision.

■ Suturing and Completion

- Nasal floor mucosal repair is performed with 6-0 Vicryl or equivalent sutures.
- Nostril sill skin repair is completed with 6-0 chromic or equivalent simple sutures up to the junction of the sill and cutaneous lip.
- A short, locking Castroviejo needle holder is useful for intranasal suturing, where access is limited.
- If the ipsilateral septal mucoperichondrial undermining has been avoided up to this point, the septum will typically be held in passive midline correction by the effect of the nasal floor repair.
- If the ipsilateral septal mucoperichondrium was inadvertently undermined,

the caudal septum may be sutured superficially to bone with an absorbable suture to maintain it in midline position.

- Palatal mucoperiosteal flaps are repaired with 5-0 Vicryl or equivalent sutures.
- Gingivoperiosteal flaps are repaired with 5-0 Vicryl or equivalent sutures (**TECH FIG 3**).
- Lip and nose repair proceed per the surgeon's preferred technique (**TECH FIG 4**).
- Vestibular tightness will normally have been eliminated by this point with nasal floor and vestibular repair allowing untethered lower lateral cartilage repositioning.
- Using medial nasal floor mucosa to line the resulting lateral vestibular defect allows anterior positioning of the cleft-side alar base so that cartilage repositioning can be achieved without posterior restraint.

TECH FIG 3 • Repaired cleft of the alveolus and lip.

TECH FIG 4 • Unilateral cleft lip and palate before (A,B) and after (C,D) gingivoperiosteoplasty along with lip and nasal repair showing the beneficial effect of formal nasal floor and vestibular reconstruction on the anteroposterior position of the cleft alar base.

PEARLS AND PITFALLS

Hemostasis

- GPOP is technically demanding and cannot be safely completed in the setting of active bleeding.
- Careful use of epinephrine-containing local anesthetic is essential.

Technique

- The anatomy of the unerupted dentition is unfamiliar to many surgeons and should be studied before attempting GPOP.
- Rough, blunt dissection of gingival flaps can easily luxate unerupted or recently erupted teeth.
- Perform gentle subperiosteal dissection over bone and sharp dissection over unerupted teeth.
- A short, locking Castroviejo needle driver is useful for suturing in tight spaces such as the nasal floor.

	■ Short radius needles such as the P2 are useful for suturing in areas with limited access.
Nasoalveolar molding	■ Close approximation of maxillary segments is critical for minimizing the growth inhibiting effects of surgery. ■ Prolonged NAM has diminishing returns because older infants are more adept at removing the device. ■ Significant skin irritation from taping the device may occur and impede identification of lip landmarks. Discontinuation of the appliance several days before surgery may be indicated for significant skin irritation. ■ The alveolar cleft gap must be diminished through alveolar molding and not through transverse collapse of the segments, as this will lead to loss of arch length and “locking in” of improper arch form.
Cleft lip and nose	■ Midline relocation of the cartilaginous septum simultaneously facilitates primary rhinoplasty and GPOP. ■ By using the primary palatal nasal lining flap to fill the lateral vestibular releasing incision, the use of nonanatomic labial or turbinate mucosal flaps is avoided.

POSTOPERATIVE CARE

- Arm restraints are used only until the effects of general anesthesia have worn off.
- A well-repaired alveolus is not at risk from the infant’s fingers.
- Feeding is resumed using the patient’s preoperative routine with the exception of limiting the use of any hard feeding implements (eg, plastic spoons and cups) or toys until primary healing is observed in the outpatient setting (typically between 10 and 14 days).
- Patients remain in hospital until normal feeding and adequate pain control are achieved (1–2 nights in most cases).
- Patients are seen in the outpatient clinic at weekly intervals until primary healing is confirmed and then at intervals otherwise dictated by early aftercare requirements of associated lip and secondary palate repairs.
- The child is subsequently seen at least yearly in the Cleft and Craniofacial Team Clinic until the end of growth and treatment.

OUTCOMES

- The NYU group studied patients treated with NAM and GPOP using Millard’s

technique at the time of primary lip repair.^{6,8}

- The alveolar cleft sites treated with GPOP did not require secondary alveolar bone grafting in 73% of cases.⁶
- Using cephalometric analysis of unilateral cleft lip and palate patients evaluated before puberty, they found no significant difference in vertical or sagittal midface growth between those receiving GPOP and those who did not.⁸
- Brusati and colleagues performed a technique of gingivoalveoloplasty in concert with palatal repair with more extensive mobilization of mucoperiosteal flaps analogous to those used in secondary bone grafting procedures.
- In a study of 87 unilateral and 29 bilateral cleft lip and palate patients, none required secondary alveolar bone grafting.¹
- In a retrospective study, 15 gingivoalveoloplasty patients were compared with 10 receiving only secondary bone grafts. An increased need for orthognathic surgery was projected for gingivoalveoloplasty patients (26.6%) vs secondary bone grafted patients (10%).²
- Interpreting studies attempting to measure the effect of GPOP on facial growth must account for the wide variability in the rate of orthognathic surgery reported at different centers.
- Daskalogiannakis and Mehta reported a 48% rate of orthognathic surgery for unilateral cleft lip and palate patients.¹²
- Such intercenter variability can relate to many factors:
 - Differing rates of syndromic diagnoses
 - Anthropometric differences between population groups under study
 - Lack of standardized orthognathic surgery indications
 - Variability in acceptance of orthodontic camouflage
 - Cultural variations in concepts of attractiveness
 - Variation in access to interceptive dental treatment
 - Changes in technique over time
 - Errors relating to incomplete records and follow-up
- Preclinical studies have demonstrated risks of neurotoxicity from exposure to common anesthetic agents.¹³
- There has been increased interest in limiting anesthesia exposure in the pediatric population while ongoing clinical studies attempt to quantify the actual risk.
- The possible detrimental effect of early anesthesia may be a consideration

when choosing between surgical lip adhesion and NAM therapy for the purpose of alveolar cleft approximation.

- The burden of multiple surgeries is significant for cleft patients. McIntyre et al. found in their single center retrospective study that unilateral cleft lip and palate patients averaged 9.4 surgeries between birth and age 21.¹⁴ Limiting numbers of surgeries may have significant benefit to patients.
- NAM therapy may be a useful means of reducing secondary operations.
 - Dec et al. found that out of 178 patients undergoing NAM and subsequent staged lip and palate repair, only four palatal fistulas occurred with only one requiring repair.⁷
- Patel et al. found that only 3% of NAM-treated unilateral cleft lip and palate patients required early nasal revision vs 21% of non-NAM patients.⁵

COMPLICATIONS

- Fistula
- Tooth injury
- Suture granuloma
- Growth restriction
- Inadequate bone formation requiring secondary bone grafting
- Infection

32 BMP Use in the Craniofacial Skeleton

CHAPTER

James P. Bradley and Kristen S. Yee

DEFINITION

- Synthesized recombinant human bone morphogenetic proteins (BMPs) have osteoinductive activity (ability to induce new bone formation) for use in the craniofacial skeleton and may replace bone grafts, which have a high morbidity, and alloplastic grafts, which are incompatible with the growing skeleton.
- Craniofacial operative procedures that utilize BMP-2 and a resorbable matrix include (a) alveolar cleft repair (both primary and secondary), (b) cranial vault defect reconstruction, and, less commonly, skeletal reconstruction, like (c) mandibular defect repair with supportive crib or (d) rare Tessier cleft repair.

ANATOMY

- Alveolar cleft defects may be unilateral or bilateral and are thought of as three dimensional (3D) trapezoid shapes that span from the floor of the nose (superiorly), to the alveolar ridge (anteriorly), to the bottom of the gingiva or adjacent tooth root with attached gingiva (inferiorly), and to the incisor foramen (posteriorly) (**FIG 1A,B**).
- Cranial vault defects vary in size and location and may be complete or incomplete; these defects have varying degrees of intervening scar from the deep dura to the more superficial periosteum, galea, or skin. Reconstructions of skull defects near the frontal sinuses or other areas lined with mucosal membranes are fraught with infectious problems.¹
- Mandibular defects also vary in size and location and present after tumor resection or as a result of complications of trauma (including nonunion and osteomyelitis).² They may be separated into anterior (symphyseal,

parasymphyseal), lateral (body, ramus), or posterior (condylar).

- Rare Tessier clefts are associated with bony defects in the facial skeleton based on defined embryologic zones numbered from 0 to 14 (**FIG 2**). Skeletal defects correlate with overlying soft tissue deficits and may extend from the maxilla, through the maxillary sinus, into the orbit and/or into the cranium. These skeletal defects benefit from bony reconstruction.

PATHOGENESIS

- Congenital: Facial clefts (common, cleft lip and palate, and rare, Tessier-numbered clefts) occur due to failure of fusion of facial embryologic elements.

FIG 1 • Intraoperative image of right cleft lip and palate patient during primary lip, nose, and GPP with BMP-2 repair. **A.** The alveolar defect is represented anatomically as a 3D trapezoid that extends from the floor of the nose (superiorly), to the alveolar ridge (anteriorly), to the bottom of the gingiva or adjacent tooth root with attached gingiva (inferiorly) and to the incisor foramen (posteriorly). **B.** The BMP-2–impregnated collagen gel fills the alveolar defect after deep mucosal flaps are closed. Careful soft tissue closure over the implant is then performed.

FIG 2 • Tessier classification of craniofacial clefts. Skeletal locations of numeric clefts are depicted on the right side of the face, and soft tissue landmarks are outlined on the left side of the face. Facial clefts are numbered 0 through 7, and cranial clefts are numbered 8 through 14. A mandibular midline facial cleft is number 30.

- **Oncologic:** Tumors in the craniofacial skeleton may arise from a variety of pathologies involving bone or adjacent soft tissue.

- Traumatic: Defects typically arise as sequelae of initial bony repair, such as nonunion, osteomyelitis, or absorption of a bone flap or graft.^{3,4}

NATURAL HISTORY

- Alveolar clefts that are not repaired (or poorly repaired) can have several consequences.
 - A persistent oronasal fistula may result in poor speech and difficult hygiene.
 - Insufficient or absent bone may prevent eruption of teeth in the cleft area and also result in malocclusion due to maxillary arch collapse.
 - Discontinuity of the maxillary arch increases difficulty of a future Le Fort I advancement.
 - Lack of bone under the nasal base results in nasal asymmetry.
- Large cranial defects necessitate the use of helmets to protect the brain and may result in the “syndrome of the trephine”—neurologic cognitive deficits related to disruption of equilibrium of intracranial pressure secondary to exposure of the brain to atmospheric pressure.⁵
- Unrepaired mandibular defects can result in difficulties with mastication and speech and an “Andy Gump” deformity, characterized by severe retrognathia and the appearance of an absent chin from contraction of the soft tissues over the area with missing bone.
- Rare Tessier craniofacial clefts repairs that do not receive adequate skeletal support will result in soft tissue collapse and progressive worsening of the deformity over time.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Alveolar cleft: An alveolar defect can be associated with nasal regurgitation and poor feeding when associated with a cleft palate or oronasal fistula; a gap or notch in the alveolar ridge is seen on examination.
- Cranial defect: The history may include head trauma or prior intracranial hemorrhage necessitating decompressive craniotomy; the edges of the bony defect are palpable, and with long-standing, large defects, the skin may be contracted into the depression (sunken skull deformity).
- Mandibular defect: The patient’s history includes prior mandibular surgical resection. The patient may report problems with mastication, oral competence, or pain. Malocclusion and soft tissue collapse can be seen on exam.
- Rare craniofacial cleft: Larger clefts can be noted on prenatal ultrasound and consultation may be planned before delivery; findings vary depending on the

site and severity of the cleft. Careful examination of the eye and lid structures, and nasal and oral cavities should be performed, particularly when the cleft is adjacent to these structures.

IMAGING

- Alveolar cleft: Although imaging should be used sparingly in infants and children due to risks of radiation exposure, a CT scan can be useful to assess the volume of the defect and the graft “take” after surgery (**FIG 3**). Routine records for secondary alveolar grafting include a panorex and periapical films.
- Cranial defect: A CT scan (1-mm cuts from the apex to the hyoid) with 3D reconstruction gives an accurate assessment of the defect size and location, as well as record of brain pathology, including ventricular size. In addition, a 3D CT scan model may be helpful for intraoperative resorbable plate shaping.
- Mandibular defect: A CT scan with 3D reconstruction, with or without model reconstruction, acts as a road map for reconstruction and guide for creation of custom-made supportive cribs (**FIG 4**).
- Rare Tessier clefts: A CT scan with 3D reconstruction is of paramount importance with these cases because of the unique skeletal abnormalities that occur within Tessier-numbered regions that the outward soft tissue findings only partially suggest.

SURGICAL MANAGEMENT

- Alveolar cleft: Primary alveolar cleft closure at the time of cleft lip or palate repair with gingivoperiosteoplasty (GPP) and BMP-2 is possible after presurgical molding approximates alveolar segments within 2 mm (**FIG 5A,B**). Secondary alveolar closure may be performed after orthodontic palatal expansion at approximately age 6 to 10 years of age.

FIG 3 • CT scan with axillary cuts of a patient with right cleft lip and palate. **A.** Preoperative image shows the alveolar defect. **B.** Postoperative image 6 months after gingivoperiosteoplasty (GPP) and BMP-2 grafting shows bony healing and closure of the alveolar defect. 3D CT scan of a patient with right cleft lip and palate. **C.** Preoperative image shows the alveolar defect. **D.** Postoperative image 6 months after GPP and BMP-2 grafting shows bony healing and closure of alveolar defect.

■ Cranial defect: Bilaminar resorbable matrix with BMP-2 reconstruction is an

alternative to titanium, alloplastic, or autologous bone reconstruction (**FIG 6A,B**). Each of these techniques provides structural support to protect the underlying brain. The bilaminar resorbable matrix with BMP-2 reconstruction has the added benefit of decreased donor-site morbidity and eventual resorption of all foreign material.⁶

FIG 4 • 3D model created for mandibular reconstruction with BMP-2 and titanium plate crib.

- Mandibular defect: The indication for BMP-2 crib reconstruction is similar to an iliac crest bone graft in that there is a defect size limit of 5 to 8 cm after which vascularized fibular bone is preferred. Importantly, this technique is not performed after oncologic resection because of concern that BMP-2 can cause unrestricted bone growth.
- Rare Tessier clefts: During the initial procedure, when soft tissue flaps are raised for repair of the cleft, there is excellent access to the osseous defect. Autologous bone donor sites may be limited at the time of this initial repair due to the patient's age, so the use of BMP-2 becomes a good option.⁷

FIG 5 • 3D Illustration of alveolar segments in a patient with left cleft lip and palate. **A.** Prenasoalveolar molding (NAM) shows collapse of the lesser segment. **B.** Post-NAM image shows approximation of the alveolar segments and creation of a normal alveolar “U shape.”

FIG 6 • Illustration of customized bilaminar construct. **A.** The bottom (endocranial) resorbable plate has supportive struts (pins); the BMP-2–impregnated resorbable sponge (*blue*) is placed between the plates. **B.** Ectocranial plate (*top plate*) is placed on top of the pins (*supportive columns*) which were previously placed through the endocranial plate and sonic welded.

TECHNIQUES

■ Alveolar Cleft Repair

Gingivoperiosteoplasty With BMP-2

- Markings vary slightly depending on whether the repair is performed at the time of the cleft lip (3 months) or cleft palate repair (10 months).
 - Alveolar segments have been approximated within a few millimeters so vertically designed flaps within the cleft are possible for closure without significant dissection.
 - Vertical markings within the cleft separate the deep gingival flaps from the anterior gingival flaps.
 - Deep flaps for palatal closure are marked as extensions of the nasal floor flaps.
 - For the inferior aspect of the gingival closure, separate triangular flaps are marked for a Z-plasty-type closure. Injection along incisions and under the flaps is performed.
- A no. 15 blade or Beaver blade is used to make the incisions. Limited subperiosteal dissection within the alveolar cleft is performed with a Freer elevator.
 - Avoid injury to tooth buds because alveolar bone is soft before age 1.
- Nasal floor closure is performed with interrupted Vicryl or chromic suture on a P-2 needle.
- Next, the deep flaps are approximated.
 - Gingival bottom flaps are transposed and sutured across the defect to the other side.
- Resorbable collagen matrix is impregnated with BMP-2 for 20 minutes and then implanted within the defect.
 - Demineralized bone matrix may be added for support if the collagen matrix is collapsible.
 - The implant is packed into the defect and at the inferior edge of the piriform aperture for alar base support.
- Anterior gingival flaps are then sutured with vertical mattress 5-0 chromic or Vicryl sutures.
 - If deep or anterior closure does not create a watertight seal, then thin

AlloDerm may be used to supplement the closure (**FIG 7A,B**).

Secondary Alveolar Cleft Repair

- Papillary (or gingivobuccal) incisions are marked, extending from within the cleft to the first molar with a backcut planned cephalad into the buccal mucosa.
- Local anesthetic with epinephrine is injected along the incisions and under the flaps.
- A no. 15 blade is used to make the incisions, and subperiosteal degloving of the maxilla and nasal region is performed with a periosteal elevator.
- With the maxillary mucosal flaps elevated, lateral backcuts are made underneath the flaps in the periosteum to provide a release for a “sliding sulcus” advancement.
 - Within the cleft, elevation of the lateral cleft flap (from the lesser segment) and the medial cleft flap (from the premaxilla), including a vomer flap, is performed in a subperiosteal plane.
 - Separation or bisection of flaps is sharply performed for intraoral palatal and nasal floor closures.
- Nasal floor closure is performed with interrupted Vicryl or chromic suture on a P-2 needle. Intraoral palatal closure is performed with vertical mattress chromic sutures.
- Resorbable collagen matrix impregnated with BMP-2 (with or without demineralized bone matrix) is implanted into the alveolar cleft defect and along the piriform aperture for alar base support.
- Lateral gingivobuccal flaps are advanced to the anterior mucosal flap for closure over the implanted graft. Dental Coe-Pak is placed as a dressing.

■ Cranial Defect Repair

- Although a coronal zigzag incision is preferred when marking, previous craniotomy incisions must be considered. Scalp hair is removed by limited clipping to access previous scars and plan incisions that maximize scalp blood supply.
- The incision is made down through the periosteum overlying the bone. In the area of the defect, an elevator is placed between the subgalea and scarred dura to protect the deep structures.
- Skin flaps are raised and subperiosteal dissection around the entire defect is

performed. Along the bony borders of the defect, a small endocranial rim is developed. Power burring is performed along the osseous borders to promote osteoconductive healing.

- A 3D CT scan skull model is helpful for shaping the resorbable mesh plates (Resorbex, KLS Martin, Jacksonville, FL) (**FIG 8A,B**).
 - The endocranial plate is placed on the endocranial side of the model, trimmed, and molded with hot saline.
 - Resorbable pins (7 mm) are placed through holes and welded to the plate as supportive columns.
 - BMP-2 is soaked onto the resorbable collagen matrix for 20 minutes and then placed with DBM around the pins.
 - The ectocranial plate is contoured to the ectocranial surface of the model allowing 1 cm of plate to overlap the in situ bone for fixation.
 - The endocranial plate is then placed on top of the pins (columns) and collagen seeded with BMP-2.
 - This is welded together with a flat sonic weld tip to create the bilaminar “sandwich” (**FIG 9A,B**).
 - The bilaminar construct is implanted into the cranial defect and sonic weld pins are used for fixation.
 - Skin flaps are closed in two layers over a drain placed away from the construct.
-

■ Mandibular Defect Repair

- A gingivobuccal incision or Risdon incision is marked depending on previous incisions.
- Recreation of the mandibular skeletal defect is performed by dissecting subperiosteally to bone and retained hardware.
 - Intervening soft tissue is excised.
 - A fresh osteotomy cut or burring at the bony edges is performed to ensure influx of preosteoblasts for implant healing.
- The titanium or resorbable crib is fashioned to outline the mandibular defect with lingual lip and complete coverage of the inferior and anterior borders.
 - The crib is secured with screws (for titanium plate) or pins (for resorbable implant).
- Resorbable matrix impregnated with BMP-2 (for 20 minutes) with or

without demineralized bone matrix is packed into the crib.

- Meticulous closure is performed with running, locking 3-0 chromic sutures.
 - Temporary placement into maxillomandibular fixation is recommended.

■ Rare Tessier Cleft Repair

- During the initial soft tissue repair when flaps are raised, there is excellent access to the osseous defect.
 - Autologous bone donor sites may be limited in infants and young children, so the use of BMP-2 becomes a good option (**FIG 10A,B**).
 - An example of this is a no. 3 or 4 rare facial cleft with ocular-sinus-oral communication.
- Soft tissue flap designs respecting natural facial aesthetic lines are used with nasal rotation, eyelid switch flaps, and lateral cheek advancement.⁷
- After injection and incisions, thick flaps are raised to ensure an adequate blood supply.
- Skeletal defects are completely dissected, and intervening soft tissue is excised. For complete clefting, deep mucosal flaps within the cleft are raised for closure.
- After closure of the deep flaps, BMP-2 is applied to collagen matrix for 20 minutes and implanted into the skeletal defect.
- Anterior flaps are rotated, transposed, and closed in layers with resorbable sutures.

PEARLS AND PITFALLS

Techniques

- Implant and construct must have enough structure to conform to the defect area and prevent soft tissue collapse into the defect.
- Complete closure with well-vascularized tissues is important for healing and to resist exposure of the implant and infection in the perioperative period.
- To limit ectopic bone formation, the implant with BMP-2 should be confined to the defect area.

Alveolar

- For primary alveolar grafting during infancy, limited dissection

defect	during GPP is required to avoid growth disturbances. ⁸ ■ “67” Beaver blade should be used to make incisions.
Cranial vault	■ Large surface area of resorbable plates may cause soft tissue swelling during resorption phase, months after healing.
Mandibular defects	■ Dental implants can be placed in select patients, months after osseous healing, but “jaw in a day” (implants at the time of free fibular reconstruction) cannot be performed. ⁴ This technique is limited to smaller defects.
Tessier Clefts	■ Bone reconstruction with BMP-2 may be performed during the initial soft tissue repair when soft tissue flaps are raised and defects are most accessible.

POSTOPERATIVE CARE

- Alveolar cleft repair: Soft diet for 1 week or until complete mucosal healing. For secondary repair, remove the Coe-Pak at 1 week.
- Cranial vault repair: Customized helmet provides protection for the first few weeks but is not absolutely necessary. Avoid contact sports for 6 weeks.
- Mandibular defect repair: Placement into MMF for a week; liquids until complete mucosal healing and then soft diet for 1 week

OUTCOMES

- Alveolar cleft repair: Francis et al. retrospectively reviewed 55 patients who underwent secondary alveolar cleft reconstruction, 36 of whom received rhBMP-2 with demineralized bone matrix (DBM) scaffold; the remainder underwent the standard iliac crest bone grafting.⁹
 - Bone stock was evaluated using occlusal radiographs. Clefts repaired with rhBMP/DBM was 97% successful (based on volumetric fill), compared with 84% in patients with iliac-derived bone grafts.
 - Patients with iliac bone grafts had a significantly higher rate of intraoral infection postoperatively.
- Cranial defect repair: rhBMP has been used in the pediatric population, for whom availability of split grafts can be limited. Beidas et al. demonstrated that the addition of rhBMP can improve rates of defect closure when added to particulate autogenous bone graft.¹⁰
- Mandibular defect repair: Sweeny et al. retrospectively reviewed 17 cases of vascularized bone grafting to the mandible for osteoradionecrosis in which

rhBMP-2 was added to the union of native bone and fibula flap. Rates of infection and malunion were similar; there was no increase in cancer recurrences noted with the use of rhBMP-2.¹¹

- Rare Tessier cleft repair: Because these clefts are rare, no randomized studies of these patients have been performed; however, early bony healing in these cases has been documented. Secondary procedures during midchildhood and at skeletal maturity for patients with rare craniofacial clefts are more common and may require grafting with rhBMP-2.

COMPLICATIONS

- Local reactions
- Graft failure
- Infections
- Wound complications¹²

FIG 7 • View of the palate and alveolar segments in a patient with left cleft lip and palate. **A.** Pre-NAM shows wide separation of the alveolar segments. **B.** Postoperative image after NAM and GPP with BMP-2 shows healing of the alveolar segments just prior to cleft palate repair.

FIG 8 • Large pediatric cranial vault defect involving the frontal, parietal, and occipital regions. **A.** 3D model created for reconstructive planning using bilaminar resorbable plate construct with intervening BMP-2. **B.** 3D CT scan 6 months after surgery demonstrates healing at the periphery and centrally. The patient demonstrated complete calvarial healing at 1 year.

FIG 9 • Intraoperative apical views during reconstruction

with bilaminar resorbable plate and BMP-2. **A.** View following placement of endocranial plates with supportive struts (pins) and BMP-2-impregnated collagen. **B.** View after ectocranial plates have been placed and fixated to surrounding bone edges.

FIG 10 • 3D CT scan of Tessier no. 4 orbitofacial cleft and accompanying inset of patient with no. 4 cleft. **A.** CT scan at birth demonstrates the osseous defect with communication between the orbit, maxillary sinus, and oral cavity. **B.** CT scan demonstrates bone healing of the maxilla and alveolus after primary soft tissue and BMP-2 repair. Orbital reconstruction is planned in the future.

- Ectopic bone formation
- Transformation in an oncologic field¹³
- In pediatric reconstructions
 - Closure of nearby facial sutures after alveolar cleft treatment
 - Closure of cranial sutures after cranial vault defect treatment¹⁰

Section IV: Mandibular Surgery

33 Costochondral Reconstruction for Absent Temporomandibular Joint

CHAPTER

Patrick A. Gerety and Scott P. Bartlett

DEFINITION

- Costochondral graft is a rib graft harvested with osseous and cartilaginous portions.
- Hemifacial microsomia (HFM) is a congenital condition in the distribution of the 1st and 2nd branchial arch embryology affecting the mandible, ear, orbit, facial soft tissue, and facial nerve function.
- Pruzansky-Kaban modified classification system¹ is a four-point scale (I, IIA, IIB, III) used to rate mandibular hypoplasia in patients with HFM.

ANATOMY

- Mandibular anatomy (**FIG 1A**)
 - Ramus: vertical, posterior height often deficient in HFM patients; often shifted medially in HFM; site of costochondral reconstruction
 - Coronoid process: insertion of temporalis muscle; affected by ramus hypoplasia
 - Condyle: may be hypoplastic or absent in HFM
 - Body
 - Symphysis/parasymphysis
 - Alveolar process

- Temporomandibular joint (TMJ; **FIG 1B**)
 - Synovial articular joint of the mandible
 - Complex multicomponent structure that includes the condyle, glenoid fossa, capsule, articular disk, lateral pterygoid muscle, and ligaments
 - Joint allows rotation and anterior translocation.
- Glenoid fossa
 - Site of mandibular articulation on the temporal bone just anterior to the external auditory meatus/canal
 - In severe HFM, this structure is absent/hypoplastic.
- Rib osteocartilaginous junction (**FIG 1C**) is located at approximately the midclavicular line. This location will allow a portion of rib that has a long osseous and shorter cartilaginous portion for mandible reconstruction.

PATHOGENESIS

- Disorder of 1st and 2nd branchial arch development causing facial hypoplasia
- Theories:
 - Stapedial artery disruption/hematoma
 - Neural crest cell migration error

NATURAL HISTORY

- The hypoplastic mandible does grow but does not attain catch-up growth and is outpaced by the normal side.²
- Facial asymmetry may worsen with growth in more severe cases.

FIG 1 • A. Mandible. B. Temporomandibular joint. C. Rib harvest. An incision is designed in the inframammary

crease to harvest an osseocartilaginous rib graft.

PATIENT HISTORY AND PHYSICAL FINDINGS

- OMENS+ classification describes abnormalities in HFM patients.³
 - Stands for orbit, mandible, ear, facial nerve, and soft tissue
 - Extracraniofacial manifestations—requires medical workup
- Mandibular hypoplasia can be variable in morphology and degree (**FIG 2A**).
 - Vertically shortened ramus—loss of posterior facial height and blunted gonial angle
 - Occlusal cant up toward the affected side
 - Loss of posterior facial width with a medially shifted mandible
 - Displaced dental midline
- Severity of mandibular hypoplasia
 - Pruzansky-Kaban classification
 - Type I: small mandible with normal morphology
 - Type IIA: mandible with a ramus that is abnormal in size and shape, but with a TMJ that is normally situated
 - Type IIB: abnormal ramus and a TMJ that is medially displaced
 - Type III: absent ramus, condyle, and TMJ (**FIG 2B**)

FIG 2 • A. Hypoplastic mandible. Features include an occlusal cant, vertically short ramus with loss of facial height, effacement of the gonial angle, and

medialization of the ramus-condyle. **B.** Pruzansky type III mandible deformity. The ramus, coronoid process, and condyle are absent.

- This classification system has been shown to have low inter-rater reliability, which is largely related to the highly variable morphology of the hypoplastic mandible in HFM. There is no system in use that has better inter-rater reliability.
- Ramus and condyle reconstruction typically performed on type IIB and type III patients

IMAGING

- Three-dimensional (3D) computed tomography (CT) of the craniofacial skeleton provides definitive assessment of mandibular morphology.

DIFFERENTIAL DIAGNOSIS

- Hemifacial/craniofacial microsomia
- Treacher Collins syndrome
- Condylar-coronoid collapse
- Condylar hyperplasia
- Hemifacial hypertrophy

SURGICAL MANAGEMENT

Preoperative Planning

- CT scan to determine mandibular and TMJ morphology
- Orthodontic evaluation and preparation

Positioning

- Supine
- Nasal intubation

Approach

- Splints delivered by orthodontist or via computer planning service
- Two-team approach:
 - Rib harvest
 - Mandibular exposure

- Surgical goals:
 - Leveling of mandibular occlusal cant
 - Alignment of dental midline
 - Creation of neo-TMJ (“pseudoarthrosis”)
 - Rigid fixation plus maxillomandibular fixation (MMF)

TECHNIQUES

■ Open Costochondral Graft Harvest

Rib Harvest (see **FIG 1C**)

- Incision: 5 to 8 cm at inframammary crease, midclavicular line.
 - Typically allows access to rib 5, 6, or 7
- Infiltration: An epinephrine-containing local anesthetic is placed in the wound at all levels including directly onto the rib to aid hemostasis and limit intraoperative narcotic use.
- Skin incision is made sharply.
- Electrocautery is used through the subcutaneous tissue and superficial fascia down and through the pectoralis major/rectus muscle fascia.
- Muscle division
 - Either the rectus muscle may be divided in the direction of the rib directly over the chosen rib or it may be divided along the direction of its fibers and retracted.
 - The senior author generally divides the muscle directly. This allows for rapid visualization of the rib and much less strenuous retraction.
- Rib dissection
 - This portion of the harvest should be performed carefully to avoid large pleural tears and defects with possible lung injury. Large defects are typically impossible to close primarily and may require local intercostal muscle flaps and/or a thoracostomy (chest) tube.
 - Many rib approaches have relied upon subperichondrial dissection, but we find this to be time-consuming, difficult, and unnecessary.
 - Maintaining perichondrium on the rib is also critical to the stability of the osteochondral junction.
- The osteochondral junction is identified as a sharp ridge medially.

- The anterior surface of the rib is now completely exposed.
- A rib dissector is now carefully rotated around the back side of the rib around the midpoint of the desired graft. This dissector is then moved up and down the rib. This is typically a fairly forceful maneuver. Dense intercostal muscle fibers that are encountered can be divided with cautery.
- The surgeon performing mandibular exposure should communicate the expected length of rib that is required.
- Length is typically 6 to 10 cm (this can be planned from the preoperative CT).
- The cartilaginous medial margin is transected with a fresh knife. Place a protective retractor on the pleural side.
 - 1 cm of cartilage should be harvested to serve as the articular surface at the TMJ. This end will be rounded before inset. The total length of the final osteocartilaginous construct is typically 7 cm.
- The rib is then elevated, and any deep muscle fibers can be cut with cautery.
- The osseous, lateral end is then cut with a bone cutter.
- The chest is examined for an air leak using saline solution in the dissection pocket with a Valsalva maneuver performed by anesthesia (typically 20-cm H₂O above peak inspiratory airway pressure for 5–10 seconds).
- The wound is closed in layers with particular attention to a quality muscle closure.
- Bupivacaine rib blocks or an On-Q pump may be used to decrease postoperative pain.
- A drain is typically not placed.

Mandible Exposure and Pocket Creation

- A submandibular incision is marked below the mandibular border, typically one to two fingerbreadths below the border (**TECH FIG 1A**).
- The incision should be infiltrated with epinephrine-containing local anesthesia.
- The incision is made sharply and extended through the platysma (**TECH FIG 1B**).
- Blunt dissection is used to expose the inferior border of the mandibular periosteum.
- The periosteum is incised with a knife or cautery.
- A subperiosteal dissection is performed with an elevator. Dissection should

be fairly wide to place a reconstruction bar.

- A tunnel is made bluntly toward the temporal bone; this will create a pocket for the rib graft.

TECH FIG 1 • Submandibular approach. **A.** An incision is placed one to two fingerbreadths below the mandibular border (one in children, two in adults). **B.** The facial vessels may need to be divided. The marginal mandibular branch is preserved by designing a low incision, dividing the platysma low after confirming with a nerve stimulator that no branches are present. The platysma is then reflected, and the inferior border of the mandible is approached.

- This can be done with a uterine sound, a Cobb elevator, or a gloved finger.
- There will not be a normal glenoid fossa present.
- Creation of a narrow tunnel that firmly ends at the temporal bone will allow articulation at the pseudoarthrosis, maintenance of posterior facial height, adequate facial width, and less chance of graft migration.
- The patient is then placed into occlusion using an orthodontic splint and intermaxillary fixation (IMF) screws. This levels and aligns occlusion and corrects midline asymmetries.

Rib Placement and Fixation

- The graft is moved to the face.
- An approximately 0.7- to 1.0-cm cartilaginous end should be kept. This should be rounded with a knife.
- The graft is then inserted into the pocket and firmly placed against the temporal bone.
- The graft should lie lateral to the mandibular body, where there will be bone-bone contact.
- The native mandible and rib graft are then fixated with bicortical screws through the rib into the mandibular body (**TECH FIG 2**).
 - A single hole of a miniplate can be used as a washer to increase the surface area of the screw head to prevent fracturing/splintering of the graft.
- Some surgeons advocate a suspension suture placed through the neocondyle and then high into the pocket.
 - This is a technically difficulty maneuver and may not be necessary with a narrowly defined pocket and good fixation.
- The deep fascia/pterygomasseteric sling, platysma, and skin are then closed in layers. A drain is not typically used.

TECH FIG 2 • A. Placement of rib graft. **B.** Rib graft in place with patient in dental splint and MMF via bone-anchored IMF screws.

PEARLS AND PITFALLS

Appropriate shape of the articular surface

- The neocondyle should be rounded to mimic a normal condyle. Costal cartilage is used to avoid bony ankylosis.

Positioning of the graft at the cranial base

- When possible, place the neocondyle in a symmetric position to the other side. This requires attention to the A-P and medial-lateral positioning. A tunnel that is too large or was made on multiple attempts may not ensure that the graft stays where intended. Positioning can be a challenge because of the curvature of the rib. Most often, the glenoid fossa is absent; therefore, the construct articulates with the cranial base just medial to the zygomatic process of the temporal bone.

Avoidance of pneumothorax

- Careful dissection directly on the rib graft, and a postoperative Valsalva check

MMF management

- Can be removed after 3 weeks if adequate internal fixation is attained. If there is inadequate fixation, then a CT scan or panorex should be used to follow bony union.

Management of posterior open bite

- This can be done after MMF is removed with either orthodontic rubber bands to brackets or bone anchors. This encourages downward maxillary growth. A splint that is progressively ground down may also be used.

POSTOPERATIVE CARE

- Pain control particularly of rib harvest site
- Perioperative antibiotics for 72 hours
- MMF with pureed diet postoperatively
- TMJ dysfunction—TheraBite⁴
 - Used if mouth opening is worse or inadequate; begins 4 to 8 weeks after surgery
 - Protocol: five 30 second stretches, 5 times per day

OUTCOMES

- Twenty-two HFM patients, 33 rib grafts, average age 7.2 years⁵
- Eighty-two percent required no additional mandibular expansion (grafting,

distraction osteogenesis).

- TMJ ankylosis was noted in one patient.⁵

COMPLICATIONS

- Infection, abscess
- Graft resorption
- Bony nonunion
- TMJ ankylosis
- Overgrowth/undergrowth

34 Prosthetic Reconstruction of the Temporomandibular Joint

CHAPTER

Anthony P. Tufaro and Srinivas M. Susarla

DEFINITION

- Alloplastic reconstruction of the temporomandibular joint (TMJ) is frequently required to address myriad issues relating to skeletal derangements,^{1–6} including arthritic conditions (rheumatoid, osteoarthritis, and post-traumatic arthritis), ankyloses, avascular necrosis of the condyle, sequelae from condylar/subcondylar fractures, benign and malignant neoplasms, degenerative joint disease, and congenital deformities (eg, hemifacial microsomia).^{2–4}

ANATOMY

- The TMJ is a diarthrodial synovial joint.
 - As a complex apparatus, it allows full range of mandibular movement.
 - The condylar head of the mandible on each side articulates with a fibrocartilaginous disc to form, in conjunction with the glenoid fossa of the temporal bone, a joint for hinge and gliding movements.
- Derangements of the disc and the condyle frequently necessitate autologous or alloplastic replacement.
- Alloplastic joint replacement is commonly used to address end-stage deformities in the adult skeleton, multiple operated joints, and those that have failed prior autologous reconstruction.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with end-stage TMJ disease can have widely variable clinical presentations.
 - Pain is a commonly reported symptom but is not, in and of itself, an

indication for surgical intervention.

- The clinical history obtained should focus on discomfort, limitation of motion, difficulties with mastication/nutrition, prior operative and nonoperative interventions, and a focused dental history relating to occlusion and parafunctional habits.
- A complete head and neck examination should be performed, with particular emphasis on evaluation of the occlusion, TMJ findings (tenderness, crepitus, maximal incisal opening, and right and left excursive movements) and tenderness of the muscles of mastication.

IMAGING

- Magnetic resonance imaging is the preferred modality for assessing disc pathology and to obtain real-time imaging of the disc position during mandibular motion.
- Thin-cut helical maxillofacial computed tomography (CT) is the preferred modality for assessing bone pathology of the joint (**FIG 1**).
 - This may be combined with angiography in cases of ankylosis, in which the ankylotic mass shares an intimate relationship with major vessels in the region (eg, pterygoid plexus, internal maxillary artery).

DIFFERENTIAL DIAGNOSIS

- Myofascial pain
- Arthritis
- Ankylosis
- Congenital deformity
- Trigeminal neuralgia
- Internal derangement of the TMJ

FIG 1 • Coronal (A) and axial (B) computed tomography views of a patient with left-sided temporomandibular joint ankylosis.

FIG 2 • Three-dimensional reconstruction demonstrating

a large ankylotic mass involving the left temporomandibular joint. Ankylosis release and arthroplasty with a stock or custom temporomandibular joint prosthesis is one approach for management.

NONOPERATIVE MANAGEMENT

- Diagnosis is the key to treatment. Patients should be evaluated by both a surgeon and a facial pain or TMJ disorders specialist.
- Many patients will benefit from trials of nonoperative therapy (muscle relaxants, nonsteroidal anti-inflammatory drugs [NSAIDs], etc.) or dental appliance therapy (mandibular repositioning appliances, occlusal equilibration, bite guards, etc.).
- Patients who fail nonoperative therapy often begin with diagnostic and minimally invasive therapeutic maneuvers (arthroscopy, arthrocentesis), with invasive interventions (arthroplasty) reserved for refractory cases or end-stage deformities.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative planning for alloplastic TMJ reconstruction involves a preoperative decision about the use of custom or stock TMJ prostheses. In both situations, a maxillofacial CT scan with thin cuts is required to visualize the local bony anatomy and for construction of three-dimensional (3D) model templates for prosthesis fabrication (**FIG 2**).
- Patients who are candidates for alloplastic reconstruction are those who have failed conservative management and have end-stage joint disease.
- Patients with active infections, those who are skeletally immature, those with muscle hyperactivity disorders (clenching and grinding), and those with active resorptive bony processes or inadequate bone stock are not candidates for alloplastic reconstruction.³

Positioning

- The operation is completed with the patient in the supine position on the operating table.
- Nasotracheal intubation is required, as the surgeon will have to verify the

occlusion intraoperatively following prosthetic replacement (**FIG 3A**).

- The anesthetist should be told not to use long-acting paralysis, as monitoring of facial nerve branches may aid with dissection.
- The nasotracheal tube is secured to the nasal septum using a 2-0 Vicryl suture.
- A moistened pharyngeal pack is not required, but may be preferred by some surgeons.
- The patient should have a mechanism for maxillomandibular fixation in place prior to initiation of the operation. This can be orthodontic appliances, Erich arch bars, or intermaxillary fixation screws.
- If intermaxillary fixation appliances are to be applied intraoperatively, it is necessary to do so before prepping and draping, so as to avoid contamination of the facial incision with oral secretions.
- Once the maxillomandibular fixation appliances are applied, the oral cavity can be sealed off with a clear plastic occlusive dressing, and the face can be prepared in the standard fashion (**FIG 3B**).
- If the surgeon anticipates using fascia or fat grafts around the prostheses, the donor site should be prepped and draped as appropriate.

Approach

- Surgeons should be familiar with three sets of approaches to the TMJ.
- Preauricular approach
 - This entails making an incision in the preauricular skin, sometimes with extension into a coronal incision, depending on the indication.

FIG 3 • Standard views of patient preparation and

positioning. A nasotracheal intubation is performed to afford access to the oral cavity for manipulation of the occlusion **(A)**. The oral cavity is isolated from the surgical field for the majority of the case **(B)**. (Reprinted from Granquist EJ, Quinn PD. Total temporomandibular joint replacement (Stock). In: Kademani D, Tiwana P, eds. *Atlas of Oral and Maxillofacial Surgery*, 2015 with permission from Elsevier.)

- The frontal branch of the facial nerve is at risk with this approach. Traction injury is the most common cause.
- This approach provides excellent visualization of the zygomatic arch, glenoid fossa, temporomandibular disc, and condylar head.
- It is often insufficient as a single approach for alloplastic reconstruction and is often combined with a submandibular approach.
- Retromandibular approach
 - This approach entails making a skin incision over the posterior border of the mandibular ramus, followed by a retro- or transparotid dissection to reach the posterior mandibular ramus.
 - Structures at risk with this approach are the retromandibular vein and branches of the facial nerve.
 - This approach affords excellent visualization of the entire posterior mandibular ramus and is a single-incision technique for reconstruction.
- Submandibular approach
 - This approach entails making an incision 2 cm below the inferior border of the mandible to see the inferior border and lateral portion of the ascending ramus. It provides limited access to the condyle and disc.
 - Structures at risk with this incision are the facial artery, facial vein, and marginal mandibular branch of the facial nerve.
 - It is often combined with a preauricular approach.

TECHNIQUES

■ TMJ Reconstruction With Stock/Custom Prosthesis

Markings

- The preferred surgical approach is marked. It is our preference to use a combination of preauricular and submandibular or retromandibular approach (**TECH FIG 1**).
 - The preauricular incision is marked from the helical insertion to immediately superior to the lobule and crosses the tragus in an endaural fashion.
 - The submandibular incision is marked by identifying the inferior border of the mandible and the mandibular angle.
 - A linear incision is marked 2 cm inferior to the inferior border; this will assist in avoiding the marginal mandibular branch of the facial nerve.
- Once the incisions are marked, the areas are infiltrated with local anesthetic with vasoconstrictor.
 - Alternatively, dilute epinephrine solution (1:100 000) may be used if there is concern about local anesthetic effects on the facial nerve branches.

Preauricular Incision and Dissection

- The preauricular incision is made first.
- A blade is used to incise through the skin and dermis.
- The next layer encountered is the superficial musculoaponeurotic system, which is contiguous superiorly with the galea. One should hug the tragal cartilage as the dissection proceeds in this layer, for the frontal branch of the facial nerve can be as close as 8 mm anterior to the tragus (**TECH FIG 2**).

TECH FIG 1 • Preauricular and submandibular/retromandibular incisions marked. (Reprinted from Granquist EJ, Quinn PD. Total temporomandibular joint replacement (Stock). In: Kademani D, Tiwana P, eds. *Atlas of Oral and*

Maxillofacial Surgery, 2015 with permission from Elsevier.)

- Once the dissection is through the SMAS, attention is directed toward identifying the superficial layer of the deep temporal fascia, which is contiguous with the pericranium superiorly and the parotidomasseteric fascia inferiorly. This layer is easily identifiable above the zygomatic arch and is distinct in its shiny white appearance.
 - Once identified, this layer can be incised at the level of the tragus and a periosteal elevator can then be used to dissect toward the zygomatic arch.
- Once the zygomatic arch is palpated, the pretragal incision can be extended inferiorly to expose the zygomatic arch. Dissection in this manner will elevate the facial nerve with the skin flap and avoid injury.
- Once through the periosteum over the proximal zygomatic arch, the dissection continues inferiorly to expose the lateral capsule of the TMJ. This dense connective tissue is incised transversely, exposing the temporomandibular disc and condylar head.

TECH FIG 2 • The preauricular dissection is initiated first. Dissection through the skin and deeper tissues is completed immediately anterior to the tragal cartilage, so as to avoid the temporal branch of the facial nerve, which crosses the zygomatic arch as close as 8 mm from the tragus.

- The disc is bluntly dissected free of its anterior, posterior, and medial attachments, and removed. Caution should be exercised when dissecting the disc posteriorly and medially, as these areas are common sources of bleeding.

- Hemostasis is achieved with bipolar cautery.
- The dissection continues to expose the condylar head and neck, in preparation for condylectomy.
- The condylar neck should be exposed to the level of the sigmoid notch. Once this has been accomplished, the wound is inspected for hemostasis and vasoconstrictor patties are placed into the bed.

Submandibular Incision and Condylectomy

- Next, the submandibular incision is made (**TECH FIG 3A**). This is done through skin and subcutaneous tissue, until the platysma is visible.
- The platysma is then divided at the same level as the skin incision and the superficial layer of the deep cervical fascia is identified.
 - This layer is developed bluntly and then incised, with careful monitoring for marginal mandibular nerve branches.
- Once through this layer, the dissection continues superiorly onto the submandibular gland capsule, toward the inferior border of the mandible.
 - The inferior border is identified, and the fibers of the pterygomasseteric sling are incised at the inferior border.
 - A periosteal elevator is used to develop a pocket lateral to the mandibular ramus, in continuity with the previously developed preauricular dissection.
- Once the zygomatic arch, glenoid fossa, TMJ, mandibular ramus, and condyle are exposed, the condylectomy is performed (**TECH FIG 3B,C**). This is done with a reciprocating saw or oscillating saw.
 - A malleable retractor is placed on the medial side of the condyle to prevent inadvertent soft tissue injury.
 - The condylar osteotomy should be obliquely oriented, starting from the sigmoid notch and angling posteroinferiorly to the posterior border of the ramus.
 - Once complete, the condyle is removed and the bed inspected for hemostasis.
- The same exposure, dissection, and condylectomy are then completed on the contralateral side (for bilateral cases).

TECH FIG 3 • A. Division of the pterygomasseteric sling to expose the mandible. (Reprinted from Granquist EJ, Quinn PD. Total temporomandibular joint replacement (Stock). In: Kademani D, Tiwana P, eds. *Atlas of Oral and Maxillofacial Surgery*, 2015 with permission from Elsevier.) **B.** Once the zygomatic arch, condyle and articular disc, lateral ramus, and inferior border are exposed, the condylectomy is marked. **C.** The condylectomy should be performed at least 15 mm below the glenoid fossa, to allow

adequate space for the fossa component and condylar prosthesis.

Maxillomandibular Fixation and Prosthesis Insertion

- Once both condylectomies and discectomies are complete, the wounds are packed with sterile gauze and covered with sterile towels.
- The surgeon, or assistant, then changes gloves and places his or her hand in the oral cavity to verify that the mandible is freely mobile (particularly important in cases of ankylosis) and that the occlusion is stable and reproducible.
- Once this is done, the patient is placed into intermaxillary fixation, and the oral cavity is again isolated from the sterile field.
- With the patient in maxillomandibular fixation, attention is now turned to inserting the TMJ prosthesis.
 - The glenoid fossa component is inserted first and affixed using the prescribed number of screws in the planning guide (**TECH FIG 4A,B**).
 - These screws are drilled under copious irrigation.
- Following insertion of the fossa component, the condylar head component is inserted through the submandibular incision and aligned with the fossa component (**TECH FIG 4C**).
 - Once the condylar head position is seated correctly (it should be oriented posteriorly and superiorly), the prosthesis is fixed using the prescribed screws.
- In bilateral cases, the procedure is repeated on the contralateral side.

Completion

- The wounds are again packed with sterile gauze and covered. The surgeon returns with glove change to the oral cavity and inspects the patient's occlusion.
- Intermaxillary fixation is now released and verified to be stable and reproducible with the prostheses in place. Once this is completed, the oral cavity is again sealed off.
- The wounds are irrigated thoroughly with antibiotic irrigation. Abdominal fat or fascia can be used to cushion the prosthesis laterally.
- A small (7–10 Fr) drain is placed, and the wounds are closed in layers.
- The throat pack is removed, and the patient is returned to the anesthetist for

emergence from anesthesia.

TECH FIG 4 • A,B. The fossa component is inserted and affixed into position after the patient has been placed into maxillomandibular fixation (*circle*). (**B**, Reprinted from Granquist EJ, Quinn PD. Total temporomandibular joint replacement (Stock). In: Kademani D, Tiwana P, eds. *Atlas of Oral and Maxillofacial Surgery*, 2015 with permission from Elsevier.) **C.** Meticulous attention to detail is required to ensure the correct orientation of the condylar component into the fossa. The insertion vector should recapitulate the natural angulation of the condyle

relative to the inferior border of the mandible.

■ Design of a Custom Prosthesis

- The surgical steps for a custom prosthesis are the same as for a stock prosthesis. The difference is in the presurgical planning.
- Once the diagnosis is established and the decision to proceed with total joint replacement is made, the surgeon obtains a high-resolution maxillofacial CT scan.
 - From this scan, a stereolithographic model of the TMJ and mandible is made.
- The condylectomies are performed on the model and the appropriate final occlusion is established.
- From this new mandibular position, the clinical engineer fabricates a wax-up model of the TMJ prosthesis (**TECH FIG 5A,B**).
 - The surgeon will inspect the models, looking for appropriate contour, size, and position.
- Once the design is approved, the wax-up models are cast into metal components (**TECH FIG 5C**).
 - These components are sterilized and ready for use.
 - Information from the 3D models and custom implants allows the engineer to provide exact screw lengths for each fixation point on the prosthesis.

TECH FIG 5 • **A,B.** Stereolithographic model with wax-up prosthesis. **C.** Cast titanium custom mandibular joint prosthesis.

PEARLS AND PITFALLS

Hemostasis	■ At various points during the procedure, problematic bleeding can be encountered. Meticulous hemostasis is necessary at all times, but particularly during the medial dissection of the condyle and disc.
Nerve injury	■ The facial nerve is at risk during any approach to the TMJ. Careful attention to the local anatomy as well as conservative dissection and nerve monitoring can help prevent injury.
Infection	■ Because a portion of the operation requires the surgeon to enter the

oral cavity, it is paramount that all members of the operative team be aware of this to avoid cross-contamination. The protocols for transitioning to intermaxillary fixation should be reviewed during the procedure briefing and roles clearly established.

Condylar malposition

- The surgeon should ensure that the condylar position is appropriate. The condylar inclination should be oriented posteriorly and superiorly.

POSTOPERATIVE CARE

- Patients are admitted to the inpatient unit for 1 to 3 days postoperatively.
- Standard postoperative pain management should be initiated. It behooves the surgeon to discuss pain management with the patient and any treating pain specialists prior to surgery.
 - Many patients with TMJ disorders use chronic pain medications.
 - Inpatient pain service consultation should be used as needed.
- Postoperative antibiotics are not indicated.
- Patients may be kept in light intermaxillary fixation with elastics or full intermaxillary fixation with wires, depending on the final occlusion and the patient's ability to reliably occlude.
- A headwrap or JawBra may be useful for reducing edema and helping with pain.
- Patients should be maintained on a soft, nonchew diet for 6 weeks postoperatively.
- Lateral and anterior posterior skull films (or panoramic radiograph) are sufficient to verify positioning of the implants and are cost-effective.

OUTCOMES

- TMJ stock prostheses have been FDA approved for more than a decade.
 - Prospective data have demonstrated that, at 3 years postoperatively, patients had decreased pain (mean of 8.5/10–2.8/10), with improved mouth opening (20–29 mm), with 99% of patients reporting that they would undergo surgery again.^{3–6}
 - Reported revision rates are below 5% and are most commonly due to infection or heterotopic bone formation.⁵ Mechanical failures are rare.
- For custom joint prostheses, the results are similar, with noted improvement in pain and mandibular motion.^{1,2}
 - Eighty-five percent of patients with custom alloplastic reconstructions

reported improved quality of life.²

- There is a paucity of long-term data regarding durability of the prostheses, but reports in the literature suggest appropriate functioning at 10 years after insertion and up to 14 years after insertion.^{2,7}

COMPLICATIONS

- Revision rates are relatively low (less than 5%) and are related to infection or heterotopic bone formation.
- Facial nerve injury is perhaps the most significant complication.
 - The risk of attendant nerve injury increases with previously operated sites or otherwise aberrant anatomy (eg, tumor, ankylosis). Meticulous dissection and intraoperative nerve monitoring are necessary to avoid nerve injury.
 - Many patients will experience a postoperative neuropraxia simply from traction. This will typically resolve within 6 to 12 weeks.
 - Frank transections should be repaired immediately (within 72 hours).
 - Delayed recognition of a nerve injury or lack of recovery after 3 months typically requires additional procedures (eyelid weights, facial reanimation) for correction of the deficits.

Osteocutaneous 35 Parascapular Flap for CHAPTER Mandibular Reconstruction

Ravi K. Garg and John W. Siebert

DEFINITION

- The parascapular osteocutaneous free flap serves as a versatile reconstructive option for composite head and neck defects involving the mandible.
- The lateral border and angle of the scapula are the most commonly used osseous flap components, although harvest of the medial scapular border has also been described.
- Soft tissue elements that may be incorporated into the flap include skin, fat, fascia, muscle such as the serratus and latissimus, and nerves, including the thoracodorsal nerve.

ANATOMY

- The parascapular osteocutaneous free flap is based on the subscapular system emerging from the distal third of the axillary artery.
- The circumflex scapular artery branches from the subscapular artery and serves as the primary blood supply to the parascapular osteocutaneous flap.
- The circumflex scapular artery can be reliably identified in the triangular fossa, which is bound by the teres major and minor muscles as well as the long head of the triceps (**FIG 1**).
- The thoracodorsal artery also branches from the subscapular artery and sends a branch to the scapular angle either directly or as a side branch of the serratus muscle branch.
- The angular artery can be useful for augmenting the blood supply of the scapular border or can be used to harvest the scapular angle as a separate osseous flap.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Determine if the patient has had previous head and neck surgery that would limit recipient vessel options or donor sites for microsurgical reconstruction.
- Assess the patient's level of function and which donor site will result in the least morbidity.
- A scapular flap may be advantageous for older patients with compromised mobility who will have greater difficulty ambulating after surgery if a lower extremity donor site is chosen.¹
- Inspect the patient's dental occlusion and determine whether any diseased dentition needs to be managed perioperatively and whether dental rehabilitation will be performed.²

IMAGING

- Preoperative CT angiography may be useful to exclude lower extremity flap options such as the fibular flap in a patient with claudication and suspected peripheral vascular disease.
- Virtual surgical planning may be helpful for complex head and neck reconstruction. A three-dimensional reconstruction of the recipient and scapula donor sites can be produced using CT imaging. Osteotomy sites at both the recipient and donor scapula locations may be planned preoperatively and a cutting jig developed to facilitate scapular contouring and inset.³

FIG 1 • Demonstration of the cutaneous branch of the circumflex scapular artery exiting the triangular fossa defined by the teres major, teres minor, and long head of triceps. The versatility of the scapular osteocutaneous flap relates to the multiple soft tissue elements including skin, fat, fascia, and the latissimus and serratus muscles that can be elevated with the flap based on the subscapular system. Additionally, the lateral scapular border is perfused by both the circumflex scapular and angular arteries, enabling separate bone flaps to be harvested.

SURGICAL MANAGEMENT

- The parascapular osteocutaneous flap is particularly useful for composite

tissue defects with a large soft tissue component.

- Multiple skin paddles and muscle flaps, including the latissimus and serratus, can be transferred with scapular bone based on the circumflex scapular artery,^{2,4} enabling reconstruction of some of the most complex three-dimensional defects.
- This flap is unique among other choices used for mandibular reconstruction including fibula, iliac crest, and radial forearm free flaps, because the lateral scapular bone is vascularized by a circumflex scapular pedicle branch independent from the branch supplying the skin paddle.
- The bone can be inset into segmental defects of the mandible or used as a mandibular onlay, whereas the skin paddle can be safely rotated up to 180 degrees in relation to the bone.

Preoperative Planning

- Determine the anticipated length of the bony deficit at the recipient site and whether a scapula flap will provide sufficient bone to reconstruct the defect.
- Discuss with the patient and surgical team the functional goals of the reconstruction. Most male patients will be able to accommodate osteointegrated implants into their scapula flaps, although some female patients will have insufficient bone stock.⁵
- Decide whether a two-team approach will be possible based on the positioning needs of the team working at the head and neck prior to transfer of the microsurgical free flap.

Positioning

- The patient is placed in the supine position for induction of general anesthesia.
- A bump is placed under the shoulder ipsilateral to the flap harvest site. This provides sufficient exposure of the upper back, and no beanbag is required for immobilization.
 - Following flap harvest, the bump may be removed, enabling a simple transfer to the supine position.
- A Z-arm is placed on the side of the operating table opposite the back (**FIG 2A**). The patient's arm will be suspended to this following sterile preparation and draping.
- The arm ipsilateral to the flap harvest site is prepped and draped in addition to the upper back.

- A Mayo stand cover is placed over the Z-arm, and this is wrapped with two rolls of gauze (**FIG 2B**).
- A sleeve is placed over the prepped arm past the level of the elbow (**FIG 2C**). The sleeve is secured with a roll of gauze wrapped from the hand up.
- Two Kocher clamps are then used to suspend the patient's arm to the Z-arm (**FIG 2D**).
- This technique avoids any areas of concentrated pressure on the arm and minimizes the risk of peripheral nerve injury.
- The back is then draped with sterile towels and sheets.

Approach

- The operative approach to raising the osteocutaneous parascapular flap depends upon the design of the skin paddle. We tend to design the skin paddle on the back along the axis of the arm so that the donor-site scar will be hidden under the arm. However, the skin paddle can be oriented in any direction around the triangular fossa.
- Once the skin paddle has been designed, we approach flap elevation and pedicle identification by raising the flap from caudad to cephalad. However, the flap pedicle may also be approached by raising the skin paddle from its lateral or medial aspect.

FIG 2 • **A.** The patient is positioned with a bump under the back on the side of flap harvest. The arm is elevated and will be suspended to a Z-arm that crosses the patient's body. **B.** The goal of the setup is to minimize pressure on the forearm and avoid complications of neurapraxia and nerve palsy. A sterile Mayo stand cover is placed over the Z-arm and secured in place with two rolls of gauze. **C.** A sterile arm sleeve is placed over the arm after it has been sterilely prepared. **D.** The sleeve is secured to the arm with a gauze roll, and then, the gauze is secured to the Z-arm using two Kocher clamps. This strategy provides plenty of cushioning for the forearm without creating any areas of focal pressure that could result in nerve injury.

TECHNIQUES

■ Flap Elevation

Flap Design

- Landmarks: lateral scapular border, teres major, teres minor, long head of triceps
- The skin paddle of the flap is designed around the triangular fossa through which the circumflex scapular artery passes.
 - A depression superior to the teres major can usually be palpated and used to identify the triangular fossa (**TECH FIG 1A**).
- The teres major measures two fingerbreadths wide and runs almost parallel to the lateral scapular border.
 - If the muscle cannot be palpated, then the lateral border of the scapula may be identified and traced just proximal to the glenohumeral joint.
 - The triangular fossa is located two fingerbreadths medial to this junction of the lateral scapular border and glenohumeral joint.
 - Confirmation can be performed with a pencil Doppler.
- A skin paddle 5 to 10 cm in width and 16 to 46 cm in length can be harvested and enable primary closure (**TECH FIG 1B**).
 - Cadaver studies have demonstrated that branches of the circumflex scapular artery emerge radially from the triangular fossa and even perfuse the anterior chest wall at least as far as the anterior axillary line.⁶ The implication is that a long skin paddle can be harvested and followed into the inframammary fold to keep the donor site discrete.

Soft Tissue Dissection

- Once the patient is prepped and draped in a sterile fashion, skin cuts are made along the outline of the elliptical skin paddle.
- The skin paddle is elevated from caudad to cephalad using electrocautery (**TECH FIG 2A**).
 - Elevation can be performed in a subfascial or suprafascial manner.
 - If additional flap bulk is desired, a subfascial dissection may be desirable and may incorporate a fascial extension beyond the borders of the skin paddle.

- Paralyzing agents are used to facilitate electrocautery dissection.
- As the superior border of the teres major is approached, a tenotomy is used to expose the border of the muscle until the cutaneous perforator to the skin paddle is identified.
- The cutaneous perforator is followed proximally to the main trunk of the circumflex scapular vessels.
 - As the vessels are traced, distinct branches will be identified that directly penetrate the lateral scapular border or that travel closely along the muscle and fascia overlying the lateral scapular border (**TECH FIG 2B**).
- Usually, the circumflex scapular artery sends two or three branches directly to the lateral scapular bone (**TECH FIG 2C**).
- A transverse branch investing the overlying scapular muscle and fascia supplies the medial scapular border and may serve as the basis for a medial scapular osteocutaneous flap.
 - We tie this branch off and prefer to use the lateral border of the scapula for reconstruction.
 - Distinct, descending branches of the circumflex scapular vessels travel along the lateral border of the scapula and are identified and preserved (**TECH FIG 2D**).
- At this point, the remainder of the skin paddle is elevated cephalad to the cutaneous branches of the circumflex scapular vessels.
 - The skin paddle is now completely free and perfused only by these cutaneous branches (**TECH FIG 2E**). This enables the skin to be moved back and forth to facilitate exposure of the lateral scapular border.
 - The skin paddle can be rested on a stack of green towels to help expose the scapular border while minimizing tension on the circumflex scapular vessels.
- The teres minor and portions of the teres major and infraspinatus muscles are dissected off the lateral border of the scapula in order to prepare the bone for osteotomy.
 - A thin cuff of muscle is left on the lateral bone in order to preserve its periosteal blood supply.

TECH FIG 1 • A. The triangular fossa, where the cutaneous branch of the circumflex scapular artery emerges, can be identified on physical examination. The teres major is pinched cephalad to the latissimus. The depression superior to the teres major is where the cutaneous branch emerges and can be confirmed with Doppler. **B.** The skin paddle to be elevated is outlined based on the course of the circumflex scapular artery. The scapula is palpated and the lateral border is marked.

TECH FIG 2 • A. After completing the skin cuts, the skin paddle is elevated from caudad to cephalad. The dissection was performed leaving some fascia over the latissimus muscle. Midway through the skin paddle elevation, the cutaneous pedicle became visible (*black arrow*). **B.** The cutaneous pedicle is followed into the triangular fossa. Here, the teres major is being retracted with a forceps and the pedicle to the skin paddle (*white arrow*) can be seen branching from the circumflex scapular artery. **C.** Further dissection of the circumflex scapular artery (CSA) reveals multiple

direct branches to the bone (*arrowheads*) and a descending branch traveling along the lateral scapular border (*white arrow*) in addition to the cutaneous pedicle (*black arrow*). **D.** The skin paddle is flipped the opposite direction and the circumflex scapular arterial branch traveling along the muscle cuff at the lateral scapular border (*white arrow*) can be easily seen. A transverse branch traveling across the scapula has been tied off (*black arrow*). **E.** The skin paddle has been dissected completely off the back now that the circumflex scapular artery is fully defined in the triangular fossa. *Arrow* points to the cutaneous pedicle.

Bone Flap Creation

- At least 1 cm of lateral scapular bone is preserved below the glenoid fossa to avoid disruption of the glenohumeral joint.
 - The area of bone to be harvested incorporates the direct bony branches to the scapula as well as the descending scapular branch, resulting in a robust blood supply to the bone (**TECH FIG 3A**).
- Electrocautery is used to divide the infraspinatus muscle directly over the portion of the scapular bone that will be harvested.
- A sagittal or reciprocating saw is then used to make transverse cuts through the bone beginning at the lateral border as well as a longitudinal cut to join these initial osteotomies.
 - An osteotome is used to release any areas of bony adherence.
- The osteotome is then levered through the caudal, transverse bone cut, exposing the subscapularis muscle on the undersurface of the scapular bone.
 - The muscle is divided parallel to the border of the bony cut, leaving the entire bony segment free with a cuff of infraspinatus and subscapularis muscle on each surface (**TECH FIG 3B**).

TECH FIG 3 • A. The segment of lateral scapular bone to be harvested is outlined with purple ink. The outline incorporates the direct bony perforators of the circumflex scapular artery in addition to the descending branch along the scapular border. The muscle is then divided down to bone along the marking, and a sagittal saw is used to perform the osteotomies. **B.** The lateral scapular bone segment has been completely freed from the donor site in addition to the cutaneous paddle. The circumflex scapular artery is seen (*arrow*) tethering the composite flap to the triangular fossa.

- The total length of lateral scapular bone that may be harvested including the scapular angle is approximately 10 to 14 cm in an adult.

Vascular Pedicle Dissection

- With the skin paddle and bony components of the flap free, the circumflex scapular vessels are now followed through the triangular fossa to gain pedicle length.
- Side branches of the circumflex scapular vessels to the surrounding musculature are ligated.
 - The pedicle can be followed to the bifurcation of the subscapular artery into circumflex scapular and thoracodorsal branches.
- The vascular pedicle is approximately 2 to 3 mm in diameter, and the pedicle length is about 4 to 9 cm.⁷

- If additional length is needed, the thoracodorsal vessels may be ligated and the subscapular artery traced to its branch point from the axillary artery (**TECH FIG 4**).
 - Alternatively, the thoracodorsal artery can be harvested and used for reverse arterial inflow, resulting in a pedicle length of 15 to 27 cm.⁸
- Once flap harvest is complete, some surgeons drill holes in the residual scapular bone and suture the teres major and minor muscles to the bone.
- One or two drains are placed over the donor site, and the back is closed in layers.

TECH FIG 4 • To lengthen the circumflex scapular pedicle (CSP), the thoracodorsal pedicle is clipped (*large arrow*) at its branch point from the subscapular artery and the subscapular artery (*small arrow*) is followed toward the axillary artery.

■ Flap Contouring and Inset

- The flap pedicle is divided and the flap is brought to the back table for any necessary osteotomies (**TECH FIG 5A**).
 - Some surgeons choose to perform osteotomies while the flap is still perfused on the back, although this does create a risk of pedicle torsion.
- To perform an osteotomy, it is important to protect the vascularized muscle

cuff in addition to the branch of the circumflex scapular artery descending along the lateral scapular border.

- A right-angled instrument can be used to dissect around the scapula bone at the planned osteotomy site (**TECH FIG 5B**).
- A wedge of bone is then excised with a sagittal saw while the right-angled instrument is used to protect the vascularized muscle cuff and flap pedicle (**TECH FIG 5C**).
- Further contouring of the osteotomy can be performed with a bur so that the bone conforms to the arch of the reconstruction plate (**TECH FIG 5D**).
- The scapula bone segments are then drilled into a reconstruction plate (**TECH FIG 5E**) or a combination of miniplates.
- The parascapular flap skin and bone are reperfused at the recipient site following completion of microvascular anastomosis (**TECH FIG 5F**).

TECH FIG 5 • A. The parascapular osteocutaneous flap has been divided and is taken to the back table. **B.** A right angle retractor is used to dissect between the vascularized muscle cuff and the scapular bone, protecting the descending branch of the circumflex scapular artery. The planned osteotomy site is marked with purple ink. **C.** An oscillating saw is used to make

a wedge-shaped osteotomy to enable the bone to conform to the reconstruction plate. **D.** Different methods of performing the wedge osteotomy to contour the scapular bone to the reconstruction plate. Once the flap pedicle and muscle cuff are protected, an oscillating saw can be used to remove a wedge of bone. This can be freehanded or performed with the help of a cutting jig. Alternatively, a straight osteotomy can be performed and a bur can be used to shave the posterior cortex. This latter method enables controlled, gradual contouring of the scapular bone until the bone segments fit together correctly. **E.** The scapular bone segments are secured to the locking, reconstruction plate using monocortical screws. **F.** The flap is inset into a segmental mandibular defect and the flap pedicle is sewn to recipient vessels in the neck (*arrow*), resulting in revascularization of the composite tissue.

■ Reconstruction of Facial Atrophy

- In addition to being used for segmental reconstruction of the mandible, the parascapular osteocutaneous flap can also be used as an onlay reconstruction for severe facial atrophy.
- The osseous component can be used to augment the jawline, while the soft tissue is used to balance the contour of the face and establish symmetry (**TECH FIG 6**).

TECH FIG 6 • This patient presented with impairment of left-sided facial growth following removal of a tumor and adjuvant radiation therapy when she was a young child. She had loss of soft tissue volume in the left midface and lower face, in addition to deficiency of the left mandibular angle and ramus. **A.** Intraoperative markings indicate areas of soft tissue and bony deficiency where the osteocutaneous flap will be used as an onlay reconstruction. The preauricular incision was used to develop a pocket for the soft tissue component of the flap, while the neck incision was used to develop a space for the osseous component of the flap and isolate the facial vessels for microvascular anastomosis. **B.** Markings for the osteocutaneous parascapular flap are demonstrated prior to flap elevation. **C.** The flap is depicted following harvest with the vascular pedicle displayed over the yellow background. **D.** Postoperative appearance following flap inset along the left face. **E.** Preoperative

appearance. **F.** Appearance 6 weeks after surgery.

PEARLS AND PITFALLS

Patient positioning

- Supine positioning with a bump behind the shoulder enables simultaneous dissection at the recipient and donor sites.
- Suspension of the arm on the side of the flap being elevated minimizes pressure points.

Cutaneous pedicle dissection

- While dissecting the cutaneous pedicle of the circumflex scapular artery from the triangular fossa, preserve the fibrofatty tissue that surrounds the pedicle.
- This fatty tissue serves as a sort of mesentery, incorporating small branches from the circumflex scapular artery at the base of the septum to the skin paddle. Preservation of this fibrofatty tissue enhances blood supply to the skin paddle.

Skin paddle elevation

- The cutaneous branch of the circumflex scapular artery will usually arise abruptly just cephalad to the teres major muscle.
- Dissection should proceed carefully at this level to avoid injury to the cutaneous blood supply.

Hemostasis

- The scapular osteotomies usually result in the most bleeding, typically from contact of the saw with surrounding muscle fibers.
- Be sure to cauterize any perforating vessels through the subscapularis muscle as it is divided.
- Bleeding will usually decrease substantially once the osteotomies are complete.

Flap pedicle dissection

- The circumflex scapular artery radiates small branches to the surrounding musculature of the triangular fossa in addition to branches to the scapular bone.
- To identify these branches without disrupting them, it helps to spread through the soft tissue perpendicular to the main axis of the pedicle.
- This strategy helps the surgeon minimize bleeding and enables him or her to decide which pedicle branches to preserve and which pedicle branches to sacrifice.

POSTOPERATIVE CARE

- Shoulder movement is permitted as tolerated after surgery.

- As patients progress, they may work on rebuilding shoulder strength and range of motion.
- An occupational therapist can be very helpful for creating a graduated program for the patient.

OUTCOMES

- Swartz is widely regarded as the first surgeon to popularize the osteocutaneous scapula flap for mandible reconstruction.⁹
 - In his series of 26 patients, 21 patients underwent mandibular reconstruction and there was a 100% flap survival rate.
- The senior author has also had 100% survival of the osteocutaneous scapular flap.

COMPLICATIONS

- The soft tissue elements of the subscapular system carry a robust blood supply. However, if soft tissue ischemia occurs, local debridement and wound care may be necessary.
- Osteocutaneous fistulas may occur and can usually be managed with local wound care.¹⁰
- When scapular osteotomies are performed, there is a risk of ischemia involving the distal scapula bone beyond the osteotomy site. Swartz described two patients who experienced nonunion due to bone loss beyond the scapular osteotomy site.⁹
- If multiple osteotomies are being planned, incorporation of both the circumflex scapular and angular arteries to the lateral scapular bone may be considered to augment the blood supply and reduce the risk of distal bone ischemia.¹

Reverse Distraction to Create a Temporomandibular Joint

36

CHAPTER

Joseph Lopez and Anand R. Kumar

DEFINITION

- Distraction osteogenesis is a process of slow bone expansion in which new bone forms between an osteotomy gap secondary to tension stresses placed across the bone gap.¹
- Functional remodeling—the process of functional tissue formation—can be used to create a neocondyle through distraction osteogenesis.

ANATOMY

- The mandible is composed of seven zones: symphysis, body, dentoalveolar, angle, ramus, coronoid, and condyle.
- The mandible articulates with the squamous portion of the temporal bone at the condyle by forming the temporomandibular joint (TMJ).
- The TMJ allows rotational and translational movement of the mandible.
- The TMJ joint is surrounded by several muscles:
 - The masseter muscle, temporalis muscle, medial and lateral pterygoid muscles elevate or protrude the mandible.
 - The superior portion of lateral pterygoid inserts on the fibrous capsule and meniscus of the TMJ (stabilizes the meniscus during movement of the mandible).
 - The inferior portion of the lateral pterygoid inserts on the neck of the condyle (helps protrude the mandible when contracting).
 - The geniohyoid muscle and the anterior belly of the digastric muscle depress and retract the mandible.
 - All muscles are innervated by cranial nerve V.

- The TMJ articular surface (articular disc) contains a dense fibrous, connective tissue known as fibrocartilage (unlike other synovial joints, which contain hyaline cartilage).
- The central portion of the TMJ articular disc (fibrocartilage) is avascular, whereas the periphery is innervated and receives a tributary of blood vessels. The retrodiskal tissue, which is responsible for the nutrition of the TMJ, are perfused by branches of the maxillary artery (posterior auricular, anterior tympanic, and meningeal medial arteries), drained by the temporomandibular veins, and innervated by the auriculotemporal and posterior auricular nerves.
- This fibrocartilage material divides the region of the joint into two spaces:
 - The upper joint space extends from the glenoid fossa to the articular eminence.
 - The lower joint space begins above the insertion of the lateral pterygoid and then spreads out over the condyle.
- The upper joint space is involved in translational movement of the mandible (arthrodial).
- The lower joint space is involved in rotational movement (ginglymus).

PATHOGENESIS

- TMJ reconstruction is required in both pediatric and adult populations. The most common conditions that often require TMJ reconstruction include TMJ ankyloses after resection arthroplasty, micrognathia/retrognathia (hemifacial microsomia), and juvenile idiopathic arthritis that can present in both adult and pediatric patient populations.
 - TMJ ankylosis refers to a pathologic condition in which the mandible is fused to the cranial fossa by bony or fibrotic tissue. TMJ ankylosis can be caused by trauma, infection, congenital deformities, idiopathic factors, or iatrogenic causes.
 - Micrognathia is a congenital condition involving an abnormally small mandible. It is associated with upper airway obstruction and tends to occur in conjunction with tongue malposition.
 - Retrognathia is a condition in which there is lack of development of the mandible; more specifically, it refers to the retruded position of the mandible in relationship to the maxilla.
 - Juvenile idiopathic arthritis (JIA): JIA is the most common rheumatologic disease in children of unclear etiology that can commonly affect the TMJ.
- Other common causes of TMJ pathology include degenerative joint disease,

traumatic injury, rheumatoid arthritis, and TMJ ablation following tumor resection.

NATURAL HISTORY

- Distraction osteogenesis for TMJ reconstruction involves moving a segment of bone, known as the transport disc, slowly away from the host bone into the defect or future TMJ location (**FIG 1**).

FIG 1 • A digital image demonstrating the transport disc in its new simulated position in the region of the newly generated TMJ joint. Note the vertical vector of distraction and the largest possible piece of bone used as the transport disc.

- The transport disc is formed from the vertical ramus remnant or angle of the mandible and is slowly moved into the glenoid fossa or neoglenoid fossa region of the temporal bone.
- New bone formation (osteogenesis) occurs at the interface between the transport disc and the host bone. The newly formed bone trailing at the leading edge of the disc forms the new ramus or condylar neck.
- Similarly, a fibrocartilagelike structure forms at the disc's leading edge. This neofibrocartilage cap becomes the new articular surface.
- Experimental studies provide support for the remodeling steps described above:

- Zhu et al.² investigated the histomorphologic changes in the newly formed condyle reconstructed by transport distraction osteogenesis in a nonhuman primate model. This study found that “bone regeneration was perfect in the distraction gap between the transport disc and the pre-existing mandible” and the resulting neocondyle was “similar to the original condyle in appearance and structure.”
- Similarly, Hikiji et al.³ investigated articular remodeling capacities of distraction osteogenesis for TMJ reconstruction in New Zealand white rabbits and found that after 8 weeks of lengthening, “mature cortical bone” formed between the transport disc and the host bone mandibular segment. Similarly, this experimental study found that a collagenous-like structure formed a cap over the leading edge of the transport segment, suggesting this may “substitute for an articular disc.”

PATIENT HISTORY AND PHYSICAL FINDINGS

- Inspection of the head and neck region
 - Assess soft tissue asymmetry or skeletal deformities.
 - Assess ear canals and tympanic membrane for primary benign or malignant disease.
 - Assess dentition for malocclusion, mobility of teeth or prosthetics, or mandibular displacement during teeth contact.
 - Assess oral mucosa for periodontal disease, mucosal lesions, or swelling.
 - Assess for overjet, overbite, or open bite.
- Neurovascular exam
 - Cranial nerves 5 and 7 are checked, particularly examining function of the lip depressors (marginal mandibular nerve). This is the most common facial nerve palsy in hemifacial microsomia.
- Palpation of the head and neck region
 - Palpation of the TMJ region to detect crepitus, clicking, or popping
 - Palpation for swelling or tenderness of the TMJ region
 - Assess TMJ range of motion (ROM). Normal measurements in adults:
 - Interincisal opening = 40 to 50 mm
 - Lateral interincisal movement greater than 10 mm on each side
 - Any restriction in lateral movement, deviation on mouth opening, or developing of an open bite should be noted.

IMAGING

- A panoramic radiograph can identify gross fractures, arthritic changes, bone cysts or tumors, malformation, or bony abnormalities.
- Computed tomography (CT) provides bone pathology information via sectional imaging in both the coronal and sagittal planes (taken in both open and closed joint positions)
- CT remains the most frequently used modality to image in 2D and 3D the abnormal bone defect or morphology. The CT can also be used to perform virtual surgical planning (**FIG 2**).
- Magnetic resonance imaging (MRI) provides soft tissue, disc, and bone pathology information. MRIs are most often used to assess soft tissue and/or synovial disease.
- Benefits of MRI vs CT:
 - Absence of ionizing radiation
 - Imaging in multiple planes
 - Adequate soft tissue detail

DIFFERENTIAL DIAGNOSIS

- Condylar resorption after orthognathic surgery
- TMJ ankylosis
- Degenerative joint disease
- Micrognathia
- Retrognathia
- Hemifacial microsomia
- TMJ resection after pathology
- Degenerative joint disease of the TMJ
- Juvenile idiopathic arthritis of the TMJ

FIG 2 • Soft tissue (**A**), bone 3D CT scan (**B**), and AP (**C**) and oblique (**D**) bone window 3D CT scans demonstrating a shortened vertical ramus (type IIB) mandible with significant distance between the malshaped condyle and the proposed glenoid fossa location.

SURGICAL MANAGEMENT

- The indications for TMJ reconstructions are fairly broad:
 - Tumor resection
 - Degenerative joint disease

- Ankylosis
- Congenital anomalies
- Unrepairable trauma
- However, the goals are fairly specific:
 - Restoration of normal occlusion and jaw function
 - Pain relief
 - Restoration of mandibular ramus height (condylion to gonion distance)
- Distraction-based TMJ reconstructions has many benefits:
 - The TMJ is reconstructed with autogenous material that is immunologically inert and therefore capable of remodeling and growth.
 - A second donor site is not required so as to minimize overall surgical morbidity.
 - Distraction osteogenesis allows jaw mobility, decreasing the risk of restricted range of motion.

Preoperative Planning

- Radiographs of the mandible should be reviewed to determine the size of distractor needed to form a properly sized defect.
- An MRI may be useful to evaluate the soft tissue surrounding the TMJ joint.
- CT is the most useful imaging study to determine the extent of vertical ramus and transport disk anatomy for securing the hardware (**FIG 1**).

Positioning

- The patient is positioned supine on the operating table with the head in extension using a shoulder roll.

Approach

- Intraoral approach (preferred approach) with cheek trocar for screw insertion
- Extraoral/submandibular approach is an alternative.

TECHNIQUES

■ Reverse Distraction for TMJ Reconstruction

Exposure and Osteotomy

- An intraoral sulcular or submandibular incision is made beneath the angle of the mandible (**TECH FIG 1A,B**).
 - Our preference is an intraoral approach in late mixed dentition (9 to 12 years-of-age).
- A partially completed transverse osteotomy of the vertical ramus remnant is made to create the transport disc (**TECH FIG 1C**).
- The medial periosteum and muscle attachments are left intact so as not to compromise the transport disc's blood supply.
- The superior surface of the transport disc is *not* adjusted because postdistraction remodeling will allow for an anatomical articular pseudosurface to form without direct shaping.

Distractor Placement and Activation

- A properly sized distractor is chosen and is attached with a single screw using the percutaneous cheek trocar system or a right angle drill/screw driver in the inferior attachment plate (**TECH FIG 2A,B**).
 - The distraction vector is then adjusted to ensure growth into the glenoid fossa.
- The remainder of the screws are placed. We prefer 1.5-mm-diameter screws that are 5 mm in length, with a minimum of three screws on each side of the osteotomy.
- After placement of all the screws, the device is activated, and the osteotomy is partially opened and then completed with an osteotome as needed. Then, the disc is ready to be mobilized.
- A separate, single stab incision in the neck region is made to externalize the activation rod (**TECH FIG 1C**).

TECH FIG 1 • A. Severe class II bite with an overjet of more than 10 mm. **B.** Transoral approach to the vertical ramus and dissection of the buccal and lingual surfaces in preparation for the horizontal osteotomy of the vertical ramus remnant. **C.** Reciprocating saw position just prior to beginning the lingual osteotomy.

TECH FIG 2 • A. Use of the transbuccal trocar for screw placement and the activation rod exit site in the ipsilateral neck, ensuring a vertical vector. **B.** Close-up view of the trocar and activation rod of the internal distraction device in place. The device is well adapted to the underlying transport disc. **C.** The distraction device is shown in place with the transport disc activated and displaced cephalad into the region of the new glenoid fossa. **D.** Postprocedure CT scans demonstrating the device in place after vertical ramus osteotomy but prior to activation during the latency period of 72 hours after surgery.

- If simultaneous removal of pathology is necessary (eg, tumor, mass, ankylosis, or degenerative joint disease resection), a separate preauricular incision can be created to facilitate the dissection.
- After a latency period of 72 hours, distraction of 1 mm daily is performed

until completion of distraction (**TECH FIG 1D**).

- End points of distraction include symmetric vertical ramus length based on clinical exam and the creation of an anterior crossbite and posterior open bite in hemifacial microsomia cases.
- Distraction is considered complete when the occlusion reaches the desired final position based on the pathology being treated.
- Once distraction is no longer needed, the activation rod is removed and the skin is allowed to close.
- After a consolidation period of 3 to 4 months, the distractor can be removed through the original intraoral incision or rarely using a separate submandibular incision.

PEARLS AND PITFALLS

Indications	■ Tumor resection, degenerative joint disease, ankylosis, congenital anomalies, and unreparable TMJ trauma
Goals	■ Restore normal occlusion and jaw function ■ Pain relief ■ Restoration of mandibular ramus height
Distractor placement	■ Accurate placement and correct distraction vector are crucial factors that can influence long-term clinical success.
Postoperative diet	■ Patients should be maintained on soft diet until the consolidation period is complete, typically 12 wk.
Postoperative physical therapy	■ Mouth range-of-motion exercises are crucial to minimize the risk of joint stiffness after distraction-based TMJ reconstruction.

POSTOPERATIVE CARE

- Postoperative physical therapy is critical since functional remodeling continues after removal of the distraction device.
- Patients are encouraged to open/close the mouth and masticate during the

distraction process.

- All patients are placed on a soft diet until the consolidation phase is complete.
- Some surgeons encourage the use of a flat plane TMJ occlusal splint while sleeping at night for a minimum of 6 months.

OUTCOMES

- Over the past three decades, only a handful of studies have explored surgical outcomes after distraction-based TMJ reconstruction.
 - Almost all of the studies have been case series.¹⁻⁶
 - No high-level evidence studies have been published.
- In one of the largest series in the literature, Schwartz et al. assessed surgical outcomes in 12 patients who underwent reverse distraction for TMJ reconstruction.
 - At an average follow-up of 32 months, all patients demonstrated evidence of “stable occlusion” with adequate range of motion and no postoperative symptoms.⁵
- Stucki-McCormick⁶ presented their outcomes in two patients who underwent transport distraction osteogenesis for TMJ ankylosis and degenerative TMJ disease.
 - At 18 months follow-up, the interincisal opening of both patients improved from 6 to 28 mm and from 5 to 45 mm, respectively.
 - None reported pain with mastication at 18 months’ follow-up, and both patients demonstrated radiographic evidence of neocondyle development.
- To date, only one study (level III evidence) has compared surgical outcomes in patients treated with distraction osteogenesis vs arthroplasty for TMJ reconstruction.
 - Gabbay et al.⁴ examined nine congenital TMJ bony ankylosis patients, four of whom underwent distraction osteogenesis and five of whom underwent arthroplasty reconstruction.
 - Because TMJ ankylosis is prone to relapse, the primary outcome of this study was the rate of relapse. At 11 months postintervention, the authors found that TMJ arthroplasty had lower rates of relapse (8% vs 48%) when compared to distraction osteogenesis.
 - Although distraction osteogenesis patients demonstrated adequate initial mean incisor openings (27.5 vs 33.4 mm), these patients relapsed to 14.3 mm by 12.5 months postdistraction.

- Given the lack of high-level evidence evaluating the role of distraction osteogenesis in TMJ reconstruction, more studies are necessary to further elucidate the efficacy of this treatment modality when compared to other options (ie, arthroplasty, vascularized bone grafts, etc.).

COMPLICATIONS

- Hardware extrusion
- Surgical site infection
- Relapse
- Facial nerve palsy
- Seroma/hematoma
- Fistula
- Poor wound healing (eg, dehiscence)

Bilateral Sagittal Split Osteotomy for Mandibular Deficiency

37

CHAPTER

Stephen B. Baker

DEFINITION

- The mandible supports the lower 16 teeth, and its position is important for occlusion, airway function, jawline aesthetics, and facial form.
- It is a U-shaped bone that has three points of contact: two condylar heads, which rest in the glenoid fossa of the skull base, and the mandibular teeth, which are in occlusion with the maxillary teeth.
- Mandibular growth abnormalities can result in malocclusion as well as other functional problems such as airway obstruction, articulation difficulty, masticatory problems, and temporomandibular joint (TMJ) problems.^{1,2}
- The bilateral sagittal split osteotomy (BSSO) is a procedure that allows movement of the mandible in an anterior or posterior direction while maintaining overlap of the osteotomized bone segments.
- The fact that the proximal and distal osteotomized bone segments overlap facilitates return to normal jaw strength and function as healing occurs.
- Dal Pont modification
 - The anterior vertical portion of the sagittal split osteotomy should be made in the region of the mandibular first molar or slightly anterior.
 - The reason for this recommendation is that the inferior alveolar nerve (IAN) is more medially positioned within the mandible in this region and therefore is less at risk of injury during the osteotomy.¹
- Hunsuck modification
 - Hunsuck proposed that the horizontal portion of the BSSO on the medial ramus did not need to extend through and posterior to the lingula.

- He proposed correctly that this portion of the osteotomy would split naturally if the posterior cut did not go posteriorly to the lingula.²

ANATOMY

- The mandible is divided into several regions: the condyle, ramus, angle, body, parasymphysis, and the symphysis.
- The lingula is a triangular bony projection on the medial surface of the mandible, immediately in front of the mandibular foramen. It provides attachment for the sphenomandibular ligament.
- The genial tubercle is on the lingual side of the symphysis and is attached to the genioglossus and the geniohyoid.
 - In a mandibular advancement, the genial tubercle will bring these two muscles forward, which may improve the airway as well as tighten submental laxity.
 - In contrast, posterior positioning may impair the airway and cause submental fullness.
- The IAN is a continuation of the third branch of the trigeminal nerve and enters the mandibular foramen, located on the medial aspect of the ramus. This nerve travels through the mandible in the inferior alveolar canal before exiting the mental foramen to become the mental nerve.
 - The mental nerve supplies sensation to the soft tissue of the ipsilateral chin with a varying degree of cross innervation to the contralateral side.
 - Of note is that the IAN is 4 to 5 mm below the mental foramen before it ascends to exit the foramen.

Angle Occlusal Classification

- Class I: Neutro-occlusion
 - Molar relationship: The mesiobuccal cusp of the maxillary first permanent molar occludes with the mesiobuccal groove of the mandibular first permanent molar.
 - Canine relationship: The mesial incline of the maxillary canine occludes with the distal incline of the mandibular canine. The distal incline of the maxillary canine occludes with the mesial incline of the mandibular first premolar.
 - Mesognathic: normal, straight face profile with flat facial appearance
- Class II: Disto-occlusion (overjet)
 - Molar relationship: The molar relationship shows the mesiobuccal groove of the mandibular first molar is *distally* (posteriorly) positioned when in

occlusion with the mesiobuccal cusp of the maxillary first molar. Usually, the mesiobuccal cusp of maxillary first molar rests in between the first mandibular molar and second premolar.

- Canine relationship: The mesial incline of the maxillary canine occludes *anteriorly* with the distal incline of the mandibular canine. The distal surface of the mandibular canine is *posterior* to the mesial surface of the maxillary canine by at least the width of a premolar.
- Retrognathic: convex facial profile resulting from a mandible that is too small or maxilla that is too large
- Class II malocclusion has two subtypes to describe the position of the anterior teeth:
 - Division 1: The molar relationships are like that of class II, and the maxillary anterior teeth are protruded. Teeth are proclined and a large overjet is present.
 - Division 2: The molar relationships are class II where the maxillary central incisors are retroclined. The maxillary lateral incisors may be proclined or normally inclined. Retroclined and a deep overbite exist.
- Class III: Mesio-occlusion (negative overjet)
 - Molar relationship: The mesiobuccal cusp of the maxillary first permanent molar occludes *distally* (posteriorly) to the mesiobuccal groove of the mandibular first molar.
 - Canine relationship: Distal surfaces of the mandibular canines are mesial to the mesial surface of the maxillary canines by at least the width of a premolar. Mandibular incisors are in complete *crossbite*.
 - Prognathic: concave facial profile with prominent mandible is associated with class III malocclusion.

PATHOGENESIS

- Variation in mandibular projection, either prognathia or retrognathia, has a multitude of etiologies:
 - Heredity
 - Congenital syndromes
 - Endocrine abnormalities
 - Neoplasms
 - Autoimmune disease
 - Trauma
- It is important to identify the etiology and ensure mandibular growth is stable

prior to performing a surgical correction.

PATIENT HISTORY AND PHYSICAL FINDINGS

- *Dental compensation* is the term used to refer to the tendency of teeth to tilt to decrease occlusal discrepancies. For instance, in a class II occlusion, dental compensation refers to the tendency of the maxillary anterior teeth to become retroclined (moving posteriorly) while the mandibular teeth become proclined (moving anteriorly).
- The degree of dental compensation is assessed with a lateral cephalometric radiograph; the degree of dental compensation must be accounted for when treatment planning for surgery.
- Surgical procedures are usually planned based on the teeth in an uncompensated position. In compensated occlusion, the degree of potential mandibular movement may be underappreciated given the relationship of the compensated occlusion.
- Mastication difficulties should be assessed. Dentally uncompensated retrognathic patients typically have an increased overjet, which compromises the ability of the incisors to cut and shear foods during mastication.
- Airway obstruction, primarily in retrognathic patients, should be assessed. It is important to inquire about any history of snoring or sleep apnea.
 - If sleep apnea has not been diagnosed but is suspected based on the patient's history, a sleep study should be obtained. Results should be incorporated into the treatment plan.
 - If sleep apnea is present, a two-jaw procedure may be indicated in order to open the airway while correcting the occlusion.
- Aesthetic considerations of orthognathic surgery are important to consider. In particular, when treatment planning the correction of a prognathic patient, it is important to be aware of the soft tissue redundancy and submental fullness that may result with posterior positioning of the lower jaw.
 - Occasionally, even though the SNB is increased and the SNA is normal, the aesthetic result may be optimized by correcting the occlusion with upper jaw advancement to optimize soft tissue draping over the underlying skeletal relationship.³
- Many syndromes are associated with mandibular deficiency and should be identified prior to treatment. Although the treatment may not require technical modifications, it is important to be aware of any associated syndromes prior to treatment.

- Lower third facial asymmetry is not an uncommon finding in patients with dentofacial deformities.
 - It is important to note whether the asymmetry is due to mandibular deviation, mandibular asymmetry, or any asymmetry of the chin relative to the mandible.
 - Additionally, there may be maxillary asymmetry associated with mandibular asymmetry, which requires movement of the upper jaw as well.
- In patients who are concerned about the aesthetic impact of insufficient mandibular projection but demonstrate a mild or minimal occlusal abnormality, advancement of the chin is a treatment option that frequently achieves the patient's aesthetic goals without subjecting them to a sagittal split osteotomy.

IMAGING

- A panoramic radiograph is a two-dimensional representation of the mandible from condyle to condyle. It is a useful screening tool for any pathology of the mandible as well as the presence of impacted third molars.
- A lateral cephalometric radiograph can be used to identify soft tissue and skeletal cephalometric landmarks to perform cephalometric analyses.
- Imaging of wrist growth plates is a useful tool to determine whether skeletal growth is complete or ongoing. Growth plate closure is an indication that skeletal growth is complete.
- The cone-beam CT (CBCT) produces three-dimensional radiographic images of the patient's face that can be used for computerized treatment planning and splint fabrication. The technology used in a CBCT allows the image to be obtained with a far lower dose of radiation compared with traditional CT scan.
 - This image is invaluable in treatment planning for the surgical approach to correct dentofacial deformities. It also aids in the fabrication of surgical splints.
- Nuclear imaging is indicated to assess bone activity. It is nonspecific but is indicative of bone activity. This allows the clinician to assess the degree of bone metabolism in the condyles.
 - Useful applications might be to monitor rheumatoid arthritic changes, fracture healing, neoplastic activity, or condylar hyperplasia.¹⁻³

DIFFERENTIAL DIAGNOSIS

- Neoplasm: Infrequently, a neoplasm may be the source of excessive mandibular growth. A neoplastic etiology typically presents as an asymmetric mandible with the teeth out of occlusion. The rapidity of tumor growth will

produce a mandibular shift that exceeds the ability of the maxillary teeth to remain in occlusion. Mandibular asymmetries without a crossbite are typically associated with more chronic processes such as hemifacial microsomia or an early history of condylar trauma.

- Trauma: Injury to a condyle before skeletal maturity may stunt growth, leading to mandibular asymmetry and a crossbite.
- Autoimmune: Rheumatoid arthritis can cause condylar resorption resulting in an anterior open bite or mandibular retrognathia. It is important to ensure good medical control of the disease prior to undertaking surgical correction.
- Developmental anomalies: Anomalies such as Pierre Robin sequence, hemifacial microsomia, or congenital syndromes may result in hypoplastic mandibles. By the time these patients are old enough to be considered for surgery, the underlying etiology has typically been elucidated and should be considered when developing the final surgical plan.
- Endocrine: Acromegaly and other hormone abnormalities can lead to anomalies of mandibular size and position.

NONOPERATIVE MANAGEMENT

- In mild cases of mandibular prognathia or retrognathia, it may be possible for the orthodontist to dentally compensate for the skeletal abnormality and produce a dental class I occlusion.
- Occasionally, extraction of premolars may be necessary to create the space necessary to move the teeth and allow for appropriate dental compensation.
- A nonsurgical approach to mandibular retrognathia frequently results in the appearance of a large nose and a weak chin. This occurs because the orthodontist has to retrocline the maxillary incisors to normalize the dental overjet. Since the incisors support the upper lip, the lip moves posteriorly as well as giving the nose an overprojected appearance.
- If these patients are unhappy with their facial appearance, rhinoplasty and a genioplasty or chin implant are methods to camouflage the underlying skeletal discrepancy of the jaws and improve facial proportions.

SURGICAL MANAGEMENT

- The author performs sagittal split osteotomies after the completion of facial growth.
- The goal of this procedure is to anteriorly or posteriorly position the lower jaw. Additionally, this procedure may be performed to improve mandibular

asymmetry.

- The main steps of the procedure are as follows:
 - Make incisions in the mandibular mucosa.
 - Perform the osteotomy from the medial ramus down the ascending ramus along the external oblique bridge to the inferior mandibular cortex.
 - Perform the sagittal split by ensuring the IAN stays within the distal segment.
 - Position the patient's teeth in a class I occlusion.
 - Verify condylar seating and align the proximal and distal segments with a bone clamp.
 - Apply rigid fixation with use of the transbuccal trocar.
 - Release the intermaxillary fixation and verify that the patient's occlusion is in the desired class I position.
 - Close the mucosa with chromic sutures and the trocar incision with a layered subcutaneous closure.
- After the occlusion has been verified and the wounds are closed, heavy elastics are used to keep the patient's occlusion stable and immobile.
 - Half of these elastics are removed 1 week postoperatively, and the remaining elastics are removed 2 weeks postoperatively.

Preoperative Planning

- Prior to performing mandibular surgery, the patient's occlusion should be leveled and aligned by the orthodontist. The anticipated occlusion can be evaluated by hand in articulating a maxillary and mandibular plaster cast to verify that the postoperative occlusion will be stable.
- Additionally, to reduce the complication of an unfavorable split, the mandibular third molars should be extracted 4 to 6 months prior to the date of the sagittal split osteotomy.
- Risks and complications are reviewed with the patient, and include the following:
 - Injury to the IAN
 - Infection
 - Need for revision surgery
 - Need for removal of titanium fixation
 - Injury to tooth roots
 - Unfavorable split possibly requiring intermaxillary fixation if rigid fixation cannot be achieved

- If the maxillary and mandibular plaster casts are placed in the anticipated position and a stable class I occlusion is achieved, a splint may not be necessary. However, if the orthodontist desires that the mandible be moved prior to orthodontic treatment, the resulting occlusion may be unstable and benefit from a splint to stabilize the mandible while the osteotomy is healing. In cases in which the occlusion does not “lock in” after the osteotomy, a splint is recommended and it is our approach to use virtual surgical planning and CAD/CAM technology to fabricate the surgical splint.⁴

Positioning

- The patient is placed supine on the operating room table, the knees are flexed at 30 degrees with a pillow, and the heels are padded with foam cushions.
- Pneumatic compression stockings are placed and their function is verified prior to induction of general anesthesia.
- Anesthesia is achieved with the nasotracheal tube sutured to the nasal septum with a 2-0 Prolene mattress suture that is padded on either side of the septum with Xeroform gauze.
 - The knot for the suture is on the same side as the endotracheal tube, and the redundant portion of the suture is then circled around the nasotracheal tube twice before being tied down to secure the tube.
- A head drape is then placed and secured to the patient’s head with 4- × 4-in. gauze underneath the anesthesia tubing (**FIG 1A,B**).
 - The anesthesia tubing is then secured to the head drape using silk tape in a way that ensures no pressure from the nasotracheal tube is applied to the nasal ala.
- Antibiotics and steroids are administered prior to the incision; local anesthesia is injected prior to prepping and draping the patient (**FIG 1C**). The epinephrine takes effect during prepping and draping so that when the incision is made, blood loss is minimal.
- We request anesthesia to achieve a mean arterial blood pressure of 55 to 60 mm Hg as long as the patient’s health can tolerate it.
- Prior to the incision, chlorhexidine oral mouth rinse is placed in the patient’s mouth and allowed to sit for 5 minutes before removal.
- Steroid ointment is applied to the lips to reduce swelling after surgery. The desired blood pressure is verified with anesthesia, and if acceptable, the procedure begins.

Approach

- The operative team is given a list of all necessary equipment as well as a summary of the steps of the operation.
- Additionally, an image of the Mayo stand with all the instruments and the position in which they are to be placed is projected on the operating room computer screen.
- The instruments are aligned in sequential order so that the scrub nurse can hand them to the surgeon efficiently.
- A headlight is extremely helpful in these cases.
- The tooth-bearing portion of the osteotomy is the distal segment, and the condylar portion is the proximal segment.

FIG 1 • A,B. A nasotracheal tube is secured with a 2-0 Prolene suture that is tied as a horizontal mattress through the septum with Xeroform gauze to reduce pressure necrosis. A surgical towel is then wrapped as a head drape and secured with silk tape to the head as shown. The tube is then resecured to the head drape with gauze padding making sure the endotracheal tube is not applying pressure to the nasal ala. **C.** Ten mL of 1% lidocaine with 1/100 000 epinephrine is injected into each side of the sagittal split site before surgical draping is performed. The injections are in the mucosal vestibule from first molar to the ramus. Lidocaine is also injected in the medial ramus and in the retromolar

trigone.

TECHNIQUES

■ Exposure

- The Molt mouth prop is placed on the nonoperative side and is opened as far as possible.
 - A sweetheart retractor pulls the tongue away from the operative side and is secured to the mouth retractor with a 4- × 4-in. gauze (**TECH FIG 1A**).
- The incision is made from the retromolar region to the first molar at least 1 cm from the teeth.
 - This will retract after being incised and will be difficult to close if made too close to the teeth.
 - A Minnesota retractor is used by the surgeon to retract the cheek while he/she is making the incision.
- A periosteal elevator is used to expose, in a subperiosteal plane, the lateral mandible from external oblique ridge to ascending ramus.
 - The posterior lateral mandible does not need to be exposed because it is not necessary and impairs the blood supply of the posterior segment.
 - The medial ramus is dissected as well. The anterior portion of the ramus is dissected to the tip of the coronoid process. Exposure in this dissection is facilitated by the use of the coronoid notch retractor.
 - A curved periosteal elevator is swept along the inferior border of the mandible to release muscular attachments that can restrict postosteotomy positioning of the mandible.
- Exposure is key to facilitating this procedure.
 - A chained Kocher is clamped to the coronoid process, and the chain is then pulled posteriorly and clamped to the head drape to retract the mucosal tissue (**TECH FIG 1B**).
 - A Seldin retractor is placed medial to the ramus and is lowered toward the mandibular body until it meets resistance from the mandibular nerve. The Seldin should be parallel to the occlusal plane and then rotated slightly in a clockwise direction on the right side (counterclockwise on the left side) to expose the medial ramus (**TECH FIG 1C**).

TECH FIG 1 • A. To optimize exposure, a mouth prop is placed and a sweetheart retractor is then positioned to pull the tongue medially. These instruments are secured with surgical gauze. The surgeon now can use a Minnesota retractor and the free hand for an instrument. **B.** Once the incision and initial dissection has been completed, a Kocher with a chain is clamped on the coronoid process to retract tissue. The

chain can be clamped to the head drape to eliminate the need for an assistant. **C.** A Seldin retractor is placed between the medial ramus and the soft tissue parallel to the occlusal plane and then is rotated so its superior border moves away from the ramus exposing the bone. The surgeon uses this exposure for the horizontal medial ramus osteotomy.

■ Osteotomy and Sagittal Split

Video p2-c037_01

Video p2-c037_04

- A reciprocating saw with a short blade is now placed against the medial ramus to cut the anterior two-thirds of the medial ramus above the mandibular foramen through the cortical bone (**TECH FIG 2A**).
- Once the medial cut is completed, the saw blade is rotated so that the cut continues in an oblique fashion to the anterior ramus; the cut then continues along the external oblique ridge down to the inferior border of the mandible.
- Ensure that the cortical bone at the inferior mandibular border is cut completely to generate a smooth split.
- A mandibular body retractor is used to optimize visualization for the vertical cut.
- The retractor can be placed anterior to the location of the vertical cut and rotated in a counterclockwise fashion so the posterior edge retracts the cheek tissue away from the area, facilitating visualization while making the cut.
- A small osteotome is used to verify that the osteotomy is complete along the horizontal portion of the medial ramus as well as the inferior mandible at the anterior portion of the osteotomy (**TECH FIG 2B**).

Video p2-c037_02

Video p2-c037_05

- A small osteotome is tapped along the osteotomy to begin to separate the segments. It is important not to tap the osteotome too deep to avoid hitting the IAN.
- Once the superior portion of the osteotomy is wide enough to fit a Frazier suction between the edges, a three-prong spreader is placed between the segments and gradually opened.
- The surgeon must ensure that the IAN is not in the proximal segment prior to the split. A sudden split could avulse the nerve if it has not been released from the inferior alveolar canal in the proximal segment (**TECH FIG 2C**).
- Under direct visualization, the osteotomes can be used to complete the split to avoid the nerve.
 - Alternatively, once the nerve is confirmed to be in the distal segment, larger fiber-handled osteotomes can be used in tandem to complete the split. They can be placed in the osteotomy site and rotated to complete the split.
- The split is verified by attaching a Kocher to the proximal segment and moving it independently from the distal segment.

Video p2-c037_03

TECH FIG 2 • A. The osteotomy is now made on the medial ramus. The surgeon should feel the nerve below the Seldin retractor to ensure the cut is above the nerve. The osteotomy is made from the medial ramus obliquely inferior as it then continues down the ramus and onto the external oblique ridge to the inferior border of the mandible. **B.** Osteotomes are then used to verify the osteotomy at the medial ramus and the inferior border of the mandible. **C.** Cadaver image of IAN in the proximal segment. It is important prior to completing the osteotomy to verify that the inferior alveolar nerve is not within the proximal segment or it may be avulsed during the split. This image shows the nerve with the proximal segment as the split is occurring. If this is noted, an osteotome is used to release the cancellous bone from the inner cortical bone to release the nerve. If the nerve is not actually within cancellous bone, it can easily be freed with a periosteal elevator.

■ Occlusal Correction and Maxillomandibular Fixation

- Once both sides of the sagittal split osteotomy are complete, the lower jaw is placed into the desired occlusion with either a surgical splint or by placing the patient's mandible in class I maximum intercuspal position.
 - It is the author's preference to use many heavy elastic bands for intermaxillary fixation. Multiple elastics provide solid fixation; if there is any occlusal shifting, the elastics will return occlusion to the desired position.
 - Wire stretches and needs to be prestretched prior to making wire loops for maxillomandibular fixation (MMF). If manipulation of the jaws during fixation moves the occlusion, wire is not elastic and the occlusion may shift while rigid fixation is applied.

- If wire loops are used, it is important that the surgeon periodically verify the desired occlusion during the fixation process.
- Avoid excessive torque when applying wire loops because the orthodontic brackets may loosen or become detached.

Video p2-c037_06

- The proximal segment is rotated with the condyle seated in the fossa to align the superior edges of the proximal and distal mandibular segments.
 - A curved Kocher is placed to secure this position by placing it posteriorly along the osteotomy sites, where there are overlapping bony segments.
- A small curved hemostat is then placed in the mouth at the area where the screws will be placed (along the superior border of the mandible posterior to the second molar).
 - The tip is pushed out toward the skin so the surgeon can palpate where the trocar incision should be placed (**TECH FIG 3A**).
- An incision is then made long enough to accommodate the diameter of the trocar without avulsing the wound.
 - A slightly longer incision that does not avulse the skin as the trocar is inserted will be aesthetically superior to a shorter incision that is avulsed as the trocar is placed through it (**TECH FIG 3B**).
- Once the trocar is in place, the trocar cheek retractor is attached (**TECH FIG 3C,D**).

TECH FIG 3 • **A.** A small hemostat is placed in the mouth adjacent to the location of the screws and is pushed toward the skin to denote the location of the trocar incision. **B.** After the incision is made, a small hemostat is used to gently spread the tissue to facilitate the passage of the trocar. **C,D.** The trocar is placed through the incision, and then, the surgeon's

finger is used to keep the tip of the trocar exposed until the cheek retractor is attached to the trocar.

■ Rigid Fixation

- The stability of MMF and occlusion is verified prior to fixation.
 - The Kocher is released and the proximal segment is rotated with the condyle so the superior edges of the segments are aligned.
 - The Kocher is then secured to hold the segments while the position is set (**TECH FIG 4A**).
 - Fixation is now applied.
- A color-coded drill is used to drill holes through the osteotomy for fixation.
 - Irrigation is applied to the drill throughout this process so as to avoid excessive heat generation (**TECH FIG 4B**).
 - It is the author's preference to place three screws in a row at the superior border, but other patterns are acceptable as long as they do not violate the IAN or tooth roots.
 - While drilling, there is initial resistance as the drill goes through the outer cortical bone, a loss of resistance as the drill enters the gap between the bone segments, a second zone of resistance as the drill goes through the cortical bone of the distal segment, and then a final loss of resistance as the drill passes through this bone.
 - The color on the drill as the second loss of resistance occurs is noted, as this indicates the length of the desired screw (**TECH FIG 4C**). If one is uncertain which color corresponds to the loss of resistance, it is recommended to use the longer length screw.
- Once three screws are applied in this manner, the same technique is applied to the opposite side.
 - The stability of MMF and occlusion is periodically checked. Occasionally, manipulation of the mandible while applying fixation can loosen wire loops and compromise the occlusion.
 - Any change in occlusion needs to be rectified prior to application of fixation.

TECH FIG 4 • A. Prior to drilling the fixation holes, the segments are positioned with the condyle seated and the superior edges of the segments aligned. A curved Kocher is placed posteriorly and an assistant squeezes the Kocher to immobilize the segments while the fixation is applied. **B.** The drill is irrigated as the holes are drilled. **C.** The drill is color coded, and each color corresponds to the length of a screw. The color of the drill as it passes through the cortical bone of the distal segment (the second loss of resistance) is noted, and the appropriate size screw is then selected.

■ Completion

- Once fixation is applied, MMF is released and the desired occlusion is verified by rotating the mandible with seated condyles to ensure the desired intercuspal position has been achieved.

Video p2-c037_07

- If occlusion is not ideal, the process is repeated until the correct occlusion has been achieved.
- If the desired occlusion has been achieved, elastics are placed to provide MMF and the wounds are irrigated and then closed with 3-0 chromic on an SH needle.
- The author typically will close the wound with a running locked suture.
- The trocar sites are closed with a deep 5-0 Monocryl and transdermal 6-0 Prolene.
- Prior to extubation, a nasogastric tube is used to empty the stomach.
- Ice packs are applied to the cheeks in the recovery room, and the head is elevated.
- No compression dressing is used.

PEARLS AND PITFALLS

Intraoral incision

- A common error is making the intraoral incisions too close to the teeth.
- The incision should be made at least 1–1.5 cm from the teeth.
- Once the mucosa is cut, it retracts, making mucosal closure difficult at the end of the case.

Incomplete osteotomy

- The most likely areas for incomplete osteotomy are at the inferior border of the mandible of the vertical cut and at the junction of the

	ramus with the posterior horizontal cut that is lingual to the ramus. ■ Each of these areas is verified with an osteotome prior to the split to decrease the likelihood of an unfavorable split.
Nerve damage	■ Prior to splitting the segments, it is important to confirm that the nerve is not within the proximal segment. ■ If a portion of the nerve remains in the proximal segment, a sudden split could avulse the nerve. If the nerve is noted to be in the proximal segment, it is not recommended to try to dissect the nerve free from the cancellous bone. This approach has a high likelihood of nerve injury. ■ In contrast, use an osteotome to separate the cancellous bone from the cortical bone in a safe plane. The nerve will remain enveloped within the cancellous bone and should be minimally traumatized.
Bad split	■ Avoiding a bad split is key to a successful BSSO. ■ Removal of mandibular third molars 6 mo prior to the osteotomy allows time for the sockets to heal, which decreases the likelihood of a bad split. ■ If the segments do not appear to be easily separating, the surgeon should verify that the osteotomies are complete. ■ Do not use excessive force, which increases the chance of an uncontrolled mandibular split. ■ If a bad split occurs, the segments can be plated to re-establish normal anatomy, and the proximal and distal segments can then be secured into the desired position with rigid fixation.
Fixation	■ Be certain the condyles are seated when aligning the proximal segment during fixation. Verify that occlusion remains in its desired position during application of fixation. ■ Wire loops may loosen and compromise the result if not corrected prior to fixation. The author prefers heavy elastics for this reason. If a shift occurs during fixation, elastics will dynamically reset the occlusion as opposed to the static nature of a loose wire.
Screw holes	■ When drilling screw holes, ensure that the drill does not stop and that the movement is smooth in and smooth out. ■ Never have the drill running without movement. ■ Any small drill whip will enlarge the drill hole and compromise the holding power of the screw.
MMF	■ Orthodontic brackets may break during the case. If the surgeon loses the orthodontic surgical lugs, another method of MMF must be employed. ■ Rather than time-consuming arch bars, the author uses the rapid

screw-anchored MMF sets. The entire arch bar can be used or individual lugs can be cut and secured with screws as needed.

- The author does not recommend MMF screws for routine use because they do not distribute forces as evenly as the screw-anchored MMF system.

POSTOPERATIVE CARE

- The patient is placed on a liquid diet for 2 weeks. Feeding is facilitated through the use of a red rubber catheter and a Toomey syringe to inject full liquids into the mouth behind the second molars. Instant breakfast, nutrition drinks, smoothies, and anything blended into a liquid are recommended. Protein powder and vitamins can be added for additional nutritional supplementation.
- Ice packs to cheeks and elevation of the head are recommended for 1 week.
- Chlorhexidine mouth rinse is used BID for 2 weeks.
- Gentle tooth brushing with a soft bristle brush can begin as soon as the patient feels comfortable enough to insert a brush.
- At the 1-week postoperative appointment, approximately half of the elastics are removed, and sutures are removed from the trocar incision.
- Two weeks after surgery, all the elastics are removed and any necessary guiding elastics are employed. Usually, the orthodontist will dictate the use of postoperative guiding elastics.
- After all elastics are removed, the patient begins range-of-motion exercises to regain normal interincisal opening.
- The patient is instructed to avoid any contact activity for 10 weeks.
 - A soft mechanical diet is instituted 2 weeks after surgery and is advanced as tolerated.
 - The patient is told to refrain from firmer foods for 8 weeks.

OUTCOMES

- The sagittal split osteotomy is a predictable method to correct underlying mandibular skeletal deformities.
- Stability of mandibular advancement is greater than that of mandibular setback.

COMPLICATIONS

- If a malocclusion intraoperatively or postoperatively is noted due to improper

condyle position during fixation or improper indexing of the splint, fixation must be removed and reapplied. It is wise to verify splint fit prior to surgery.

- Paresthesia or anesthesia of the lip may occur from injury to the IAN. Postoperative sensory disturbances in the lower lip and chin have been reported to occur in 9% to 85% of operated sides.⁵ The lack of standardization of objective methods and time to the evaluation of sensory dysfunction after BSSO results in a vast range of prevalence of neurosensory disturbance at 1 or 2 years postoperatively (0% up to 85%).⁶
- The incidence of bad splits has been shown to be 2.0% per site. The only predictive factor for a bad split is the removal of third molars at the same time as BSSO. There is no significant association between bad splits and age, sex, class of occlusion, or the experience of the surgeon. It has been demonstrated that doing a BSSO with splitters and separators instead of chisels does not increase the risk of a bad split and is therefore safe with predictable results.⁷

38 Inverted L Osteotomy for Mandibular Surgery

CHAPTER

Raymond J. Harshbarger

DEFINITION

- Various procedures have been developed to alter the shape and position of the mandible, including the sagittal split osteotomy, vertical ramus osteotomy, and inverted L osteotomy (ILO).
- The ILO allows separation of the proximal condylar bearing segment and the distal occlusal bearing mandibular segment, for advancement of the distal segment.
- Improvements with distal segment advancement:
 - Enhancement of airway space at the tongue base, thus improving breathing functions
 - Treatment of class II dentofacial deformity, establishing abnormal bite, chewing, and speaking

ANATOMY

- The mandible is a ring structure articulating with the skull base at the glenoid fossa.
- In addition to bearing responsibility for the foundation of the lower third of the face, the mandible contains the lower dentition, and the inferior alveolar nerve transverses the marrow space through the ramus and body.
- Pertinent features on the lateral (buccal) surface of the mandible include the anterior/posterior ramus, sigmoid notch, condylar process, and coronoid.
- Medially, key landmarks include the sigmoid notch, lingua, mandibular foramen, and position/occlusal surface of molars.
- The marginal mandibular nerve changes position depending on patient age: in neonates, the marginal mandibular nerve travels along mandibular border; with

increasing age, the nerve migrates inferiorly. By skeletal maturity, the nerve is about two fingerbreadths below the mandibular border.

- The lingula is present along the medial surface of ramus and is halfway from anterior to posterior ramus and halfway down from sigmoid notch to mandibular border. It is found 1 to 1.5 cm cephalad to molar occlusal surface, in skeletally mature individuals.¹⁻³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients who benefit from ILO are generally divided into two groups:
- Neonates and children:
 - May present with airway obstruction, difficulty feeding, gastroesophageal reflux, and failure to thrive
 - Physical examination demonstrates micrognathia, glossoptosis, and possible cleft palate.
- Skeletally mature patients:
 - May have had a history of obstructive sleep apnea, TMJ disorder (with pain), and chewing and speaking dysfunction
 - Physical examination demonstrates a sagittal deficiency of the lower third of the face with class II malocclusion.

IMAGING

- Computed tomography demonstrates sagittal deficiency of the mandible. Typically, other components exhibit normal morphology.
- Operative airway evaluation (rigid and flexible exam) is done to assess glossoptosis, tongue-based airway obstruction, and prolapsed epiglottis. An anterior tongue pull and jaw thrust will improve the obstruction.

DIFFERENTIAL DIAGNOSIS

- Pierre Robin sequence
- Craniofacial microsomia
- Treacher Collins
- Micrognathia
- Juvenile rheumatoid arthritis

SURGICAL MANAGEMENT

- Candidates for ILO include patients with sagittal deficiency of the mandibular body, including neonates, children, and skeletally mature patients. Distraction

may be performed in all three groups. Orthognathic surgery is indicated in skeletally mature patients; ILO may be chosen over a sagittal split osteotomy, or vertical ramus osteotomy, especially when dealing with patients who have asymmetric skeletal findings. With a single-step mandibular advancement, bone grafts are used to bridge the created gap.

Preoperative Planning

- Neonates
 - Computed tomography
 - Operative airway (rigid/flexible) evaluation
 - Polysomnography
 - Possible virtual surgical planning with creation of operative cutting and positioning guides
- Children and skeletally mature
 - All of the above
 - Placement of orthodontic appliances, with preparatory orthodontics

Positioning

- Neonates: Supine position, with head on a gel roll, a shoulder roll, neck in extension, and an oral ET tube that is microcuffed. ET tube should be taped to the upper lip, brought cephalically, and fixed at the hairline over egg crate foam with 2-0 silk. Eyes are protected with Tegaderm (**FIG 1**).
- Children and skeletally mature patients: Nasal RAE tube sutured at the septum and at the hairline over egg crate foam with 2-0 silk. A shoulder roll should be placed, with eyes protected using Tegaderm. The patient's head should be placed on a gel roll or foam.

Approach

- The ILO technique may be approached from either an extraoral or intraoral incision or both.

FIG 1 • Patient positioning (neonatal) for extraoral inverted L osteotomy.

TECHNIQUES

■ Extraoral Inverted L Osteotomy

Exposure

- This technique is commonly used for mandibular distraction osteogenesis.
- Incision marking is designed to facilitate the osteotomy and protect the marginal mandibular nerve.
- In neonates, the neck is placed in extension; palpate the mandibular angle, marking the incision one finger breadth below the angle. Starting posterior to anterior at the angle and maintaining one fingerbreadth below the mandibular border, the incision should be 2.5 cm in length. It may be helpful to dot the midline of the neck, to view the projected path of each incision, and to improve symmetry (**TECH FIG 1A**).
- In children and skeletally mature patients, a similar approach is used; however, with increasing age, begin increasing the distance between the

mandibular border and incision placement, migrating caudally to a position of two fingerbreadths below the border in adults.

■ Vasoconstriction:

- To protect the marginal mandibular nerve and promote a bloodless field for surgery, a saline and epinephrine mixture is used. The nerve will then be responsive during dissection. Despite proper incision placement, the nerve can be encountered during approach to the mandible. There will be a greater chance of nerve preservation if it remains active during surgery.

■ Incision and approach in neonates and children undergoing distraction

- After adequate epinephrine effect, the skin is sharply incised with a 15 blade.
- Monopolar current on cutting is used to dissect through the fat and platysma muscle (dissection should be in a straight posterior direction).
- Look for the submandibular gland and any evidence of the marginal mandibular nerve. Dissect through the investing fascia of the submandibular gland, and then begin a cephalad plane of dissection (**TECH FIG 1B**).
- Tenotomy scissors may be used during these steps to help orient the surgeon, and expose critical structures such as the submandibular gland, marginal mandibular nerve, and the facial artery/vein.
- The dissection at this point should be aimed toward the mandibular angle. This is a “safe zone” to approach the mandible.
- As the facial vessels are encountered running vertically in the field of dissection, leave them intact and generally reflect them anteriorly, although posterior reflection may be performed. Once the mandibular angle is encountered, use a small toe-in retractor.
- Incise horizontally just above the mandibular border, and enter the subperiosteal plane. The lateral surface of the mandible can now be exposed using a periosteal elevator (the author prefers a small Obwegeser elevator) (see **TECH FIG 1B**).
- Mandibular exposure is complete when all key landmarks are exposed, including the anterior and posterior ramal borders, proximal portion of condylar process, and sigmoid notch and body.

Osteotomy

- The proposed osteotomy can now be marked using a sterile no. 2 pencil.
- Marking considerations include device footplate position, vector, and

avoidance of the inferior alveolar nerve as well as tooth buds (**TECH FIG 2A**).

- The vertical portion of the inverted L is marked first. For a sagittal or sagittal-oblique vector, the device is best brought out posterior and inferior to the ear lobule.
- An anterior exit for the device is also possible but can lead to increased problems with incision healing, and contamination, especially in children with a tracheostomy.
- For a posterior device exit, create a tunnel in the subcutaneous plane from the deep pocket of dissection posterior and inferior to the auricle, exiting the skin through a stab incision.

TECH FIG 1 • A. Markings for incision. **B.** Submandibular approach to expose the mandible. Note anatomic layers and plane of dissection deep to the marginal mandibular branch of the facial nerve.

- A turning arm is attached to the device (preferred is KLS Martin microZurich with rigid externally removable arm).
- The device is placed into the field, bringing the turning arm through the tunnel and skin and positioning the device over the mandible near the angle. The desired vector is determined, with positioning of the footplates to allow

placement of three screws in each footplate.

- A line is marked between the footplates, and the device is removed from the field. This mark is extended into the vertical portion of the osteotomy, running from the mandibular border to immediately caudal to proximal condylar process. The mark should be roughly parallel to the posterior ramal border.
- The upper extent of the vertical mark is made immediately proximal to the condylar process.
- Identify the convexity in the ramus, caudal to the sigmoid notch. Proximal to the vertical flattening of the convexity is a safe place to orient the horizontal portion of the osteotomy (this places the osteotomy above the lingula and tooth buds).
- The horizontal mark comes off the anterior ramus roughly perpendicular to the border and intersects the upper extent of the vertical component (see **TECH FIG 2A,B**).
- Generally, the lingula of the ramus is at the halfway point posteriorly and caudally from the sigmoid notch to the inferior border.
- Once properly marked, the sagittal saw is used to complete the vertical and anterior portions of the inverted L, saving the posterior cortex for a few millimeters anterior to the intersection of the vertical and horizontal limbs (**TECH FIG 2B,C**).
- The sagittal saw is preferred due to the limited kurf compared to the reciprocating blade.
- Next, position the device straddling the footplates on either side of the vertical aspect of the osteotomy near the mandibular border.
- The device is positioned along the ideal sagittal or slightly oblique vector (the orientation of the vertical limb of the osteotomy dictates this). Make sure the device is “zeroed” prior to positioning.
- If a more vertical vector is planned, the osteotomy needs to be a stair-step variation of the inverted L.
- Subsequent to device positioning, place three self-drilling high-profile screws in each footplate. (Length of the screws will be 5 mm in neonates and infants, but may be 7 mm in children and skeletally mature individuals.)

A

TECH FIG 2 • A. Anatomic landmarks for inverted L osteotomy. Shaded (*red*) is area of subperiosteal exposure. Relationship of inferior alveolar nerve and tooth buds to osteotomy (*dashed line*) is shown. **B.** Inverted L osteotomy, buccal view. **C.** Posterior lingual view.

- Place an Obwegeser elevator underneath the proximal (condylar) segment for support when placing screws in this segment, to avoid shearing of the posterior ramus from the condyle.
- After the device is secured to the mandible, use a mini-osteotome to separate

the posterior cortex near the intersection of the horizontal and vertical limbs (the portion remaining intact after sagittal saw use).

- Confirm completion of the osteotomy by activating the turning arm of the device. If the device turns freely, then the osteotomy is complete. Resistance may be encountered. Use the mini-osteotome to identify and separate the unfractured posterior cortex.
- After confirming osteotomy completion, return the device to the zero position, and activate the ratchet mechanism (prevents down-turning of the device, essentially undoing the distraction).
- Irrigate the operative pocket with saline, and approximate the platysma and dermis.
- Note: VSP may be used to optimize osteotomy and device position. This should allow for the production of operative guides to delineate osteotomy and device position.
- A similar procedure is performed on the contralateral side.
- The contralateral device should be placed along the same vector as the first operative side.
- To achieve device symmetry, estimate the proposed vector, place one screw, center the head, and palpate the rod of each device, rotating the newly applied device to achieve a parallel vector; then apply the remainder of screws.
- If VSP is used, apply footplate drill hole positioning guide, drill the desired holes, remove, and apply the device.

■ Combined Extraoral-Intraoral Inverted L Osteotomy

- The above approach is reliably used in neonates and young children. Older children and skeletally mature individuals undergoing mandibular distraction may benefit from a combined extraoral-intraoral approach.
- The horizontal limb of the inverted L can be difficult to reach from a submandibular approach in older patients.
- The extraoral portion of the surgery is similar to neonates and infants, except that the initial incision migrates lower with increasing age to nearly 1 in. below the mandibular border in skeletal maturity.

- To complete intraoral access, be certain the patient has full muscular relaxation, and place a bite block on the contralateral side.
- Incise the buccal mucosa with a cuff to the attached gingiva near the first molar, extending the incision vertically to immediately below the maxillary occlusal plane.
- Achieve a subperiosteal plane of dissection; then skeletonize the soft tissue from the ramus of the mandible on both the buccal and lingual aspects.
- On the medial aspect of the ramus, identify the lingula (**TECH FIG 3**).
- If the extraoral component was performed first, connect the dissection, creating a single surgical pocket.
- For those less familiar with the dissection, the intraoral component may be performed first, so that finding the proper plane from the extraoral approach is facilitated.
- Mark the vertical portion of the osteotomy as described above.
- Under direct visualization, mark the horizontal limb of the inverted L above the lingula and connect to the markings of the vertical limb.
- Complete the vertical osteotomy with the sagittal saw.
- The horizontal osteotomy remains incomplete (save the posterior cortex near the vertical-horizontal junction).
- The device can be positioned (as in earlier description) with turning arm placed either anterior or posterior.
- Affix device to mandible with self-drilling screws (use the above description for details).

TECH FIG 3 • Surgical view for intraoral inverted L osteotomy.

■ **Intraoral Inverted L Osteotomy**

- Skeletally mature patients undergoing orthognathic procedures may benefit from a completely intraoral approach to the ILO.
- Approach is through a buccal sulcus incision as mentioned in the above section.
- Once the mandible is skeletonized and the lingula visualized, mark the horizontal limb above the lingula and the vertical portion posterior to the lingula, parallel to the posterior ramal border (**TECH FIG 4**).
- The horizontal osteotomy is completed with the reciprocating saw, whereas the vertical limb is cut with a fan blade oscillating saw.

TECH FIG 4 • Lingual view illustrates relationship of osteotomy to lingula.

Mandibular anatomy	■ Complete understanding of mandibular anatomy is critical to perform a safe and effective inverted L osteotomy. This includes the location of the lingula and tooth buds/teeth.
Facial nerve anatomy	■ Intimate knowledge of craniocaudal and depth location of the marginal mandibular nerve is important in accessing the mandible for extraoral inverted L osteotomy.
Condyle and proximal segment relationship	■ Prevention of shear fractures in the proximal segment—which inadvertently separate the condyle from the ramus—is key to a successful inverted L osteotomy.
Changes in soft tissue and bone anatomy with growth	■ There are notable differences in marginal mandibular nerve position, bone anatomy and strength, in the growing craniofacial skeleton.

POSTOPERATIVE CARE

- Immediate postoperative care for ILO patients will vary depending on the age of the patient, indications for the procedure, and the type of skeletal fixation utilized.
- Neonates/infants: A mandibular distractor will be applied after the osteotomy, by providing semirigid fixation across the osteotomy. Bacitracin ointment is applied to the device exit site. Incisions are covered with Steri-Strips. During distraction, the patient is fed through an NG tube and kept intubated for a few days to allow the airway to improve. Timing of extubation is determined by the surgeon in concert with the multidisciplinary team.
- Children: At this age, patients are often extubated immediately after surgery, by virtue of the fact that they have a tracheostomy or are capable of protecting their airways. Incision care is similar to neonates.
- Skeletally mature patients: Patients are often undergoing orthognathic surgery, in which case they will have some form of maxilla-mandibular fixation (MMF) post-surgery. Most of these patients will have an intraoral incision, which requires a Peridex rinse daily.

COMPLICATIONS

- *Marginal mandibular nerve*—Temporary neuropraxia is common; permanent palsy is possible when performing extraoral ILO.
- *Inferior alveolar nerve injury*—Placement of the vertical or horizontal portion

of the osteotomy in proximity to the lingula can lead to inadvertent damage to the nerve by the reciprocating, sagittal saw, or Sonopet.

- *Tooth bud injury*—Anterior displacement of the vertical portion of the osteotomy in neonates/children may result in damage to developing dental structures.
- *Undesired fracture*—Neonates are especially susceptible to this occurrence as their mandibles are thin. Inadvertent fracture of the coronoid process will not hamper the outcome; however, separation of the condyle from the proximal segment will cause failure of the operation and requires immediate correction, by plating the disjoined segments with resorbing fixation in neonates and titanium in older children.
- *Infection*—Extraoral ILO with distractor placement can result in cellulitis/purulence at the device skin exit site and can generally be treated with antibiotics/irrigation. In most cases, return to the operating room is not required.

39 Intraoral Vertical Ramus Osteotomy of the Mandible

CHAPTER

Deepak G. Krishnan and Haithem M. Elhadi Babiker

DEFINITION

- The vertical ramus osteotomy of the mandible performed intraorally is a popular and simple technique used to achieve mandibular setback in patients with prognathism or asymmetry.
- A variation of this technique was described first by Limberg in 1925.¹ Many others have attempted to modify his approach and found that it can be performed intraorally and can be used to reduce the horizontally excessive mandibular ramus.
- A version of the vertical ramus osteotomy performed through a neck incision was popularized by Caldwell and Letterman in the 1950s.²
- In 1968, Winstanley performed the first intraoral vertical ramus osteotomy (IVRO).³ It was the work of Hall and McKenna⁴ in the 1970s that simplified, refined, and thus popularized the procedure.

ANATOMY

- The mandible is the horseshoe-shaped bone that forms the structural foundation of the lower third of the face. It is the only movable bone of the skull, articulating with the temporal bones at the temporomandibular joints.
- It consists of a horizontal curved body and two broad and oblong rami projecting upward. The alveolar processes of the mandible house and support the mandibular teeth.
- The inferior alveolar nerve enters the mandibular foramen on the medial surface of the ramus near its center.
- It then runs downward and forward within the body of the mandible and exits at the mental foramen, which is located on the external surface midway

between the alveolar process and the lower border, in the interval between the premolar teeth.

FIG 1 • A. Facial aspect of mandible demonstrating a small anatomic elevation in bone referred to as antilingula. **B.** Lingual aspect of mandible demonstrating position of lingula and the mandibular foramen.

- The anteromedial margin of the mandibular foramen is guarded by an upward tonguelike projection, the lingula.
- Along its course, the inferior alveolar nerve innervates the mandibular teeth and associated soft tissue and terminates as the mental nerve, which supplies sensation to the skin and mucous membrane of the lower lip and chin.
- The muscles of mastication directly attach to the surface of the mandible. The masseter and medial pterygoid muscles attach to the lateral and medial surfaces of the ramus, respectively.
- These two muscles together form the pterygomasseteric sling, which straddles the mandibular ramus.
- The temporalis muscle reaches into the external oblique ridge along the rami

through its tendons and helps with opening and closing of the jaw.

- The lingual nerve, before reaching the tongue, comes in close contact with the inner surface of the alveolar border of the mandible in close proximity to the mandibular third molar tooth.
- An antilingula or the antilingular prominence is a lateral bony protuberance that approximately corresponds to the lingula and the entry of the inferior alveolar nerve into its canal, on the medial aspect of the mandible (**FIG 1**).
 - This is a useful but not an entirely reliable landmark in this technique.
 - The position of the lingula is posteroinferior relative to the position of the antilingula. This has been substantiated in cadaver studies.⁵

PATHOGENESIS AND NATURAL HISTORY

- Mandibular prognathism is a condition wherein the mandible is positioned anterior to the maxilla resulting in a malocclusion.
- In the NHANES study (1989–1994), 0.3% of the US population was reported to have mandibular prognathism severe enough to require orthodontic-surgical treatment.
- About 14% of the youth in the United States have a class III malocclusion. Roughly a quarter of these patients have an isolated mandibular prognathism, whereas the remaining three-quarters have a combination of maxillary deficiency in addition to mandibular protrusion.
 - Often, a midface deficiency is wrongly diagnosed as mandibular prognathism, whereas in reality upon cephalometric investigation, the mandibular position may be normal.
- Mandibular prognathism causes aesthetic concerns, in addition to chewing and speaking difficulties, leading patients to seek surgical treatment at a younger age.
- In cases of severe mandibular prognathism, bimaxillary surgery is the preferred method of treatment (mandibular setback combined with maxillary advancement).
 - This is because excessive mandibular setback may result in obstructive sleep apnea and is also subject to higher rates of relapse.
- Mandibular growth can occur until late teens and early 20s in young men and several years past menarche in women.
 - Surgery should be deferred until there is proof of growth cessation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present during the teenage years.
- The main functional complaints related to chewing and deglutition, difficulty with speech and enunciation, and TMJ dysfunction in addition to the aesthetic concerns. Often, the malocclusion also presents as an open bite.
- The patients are usually first seen by an orthodontist and eventually referred to a surgeon when ready for surgery.
- Orthodontic treatment is usually undertaken for about a year and serves to align the teeth in the dental arches and remove any dental compensation.
- Surgery is undertaken when the patient reaches skeletal maturity (girls 16–18 years, boys 18–20 years).
- When working up for an IVRO, it is useful to note the functional status of the patient's temporomandibular joints (TMJs). The IVRO may be preferred in patients with TMJ dysfunction over a bilateral sagittal split osteotomy (BSSO), because the condyle seats itself passively in an unloaded position during healing.
- Patients with a V-shaped mandible as assessed from a *norma basalis* are probably better candidates for an IVRO as opposed to a BSSO for a mandibular setback (**FIG 2**).
- The preoperative workup includes records that replicate the relationship of the jaws to the skull base, and model surgery to fabricate the surgical splints.
 - Unlike in a BSSO, a splint may not be required in an IVRO in patients with stable occlusion and orthodontic setup.
 - In the case of double-jaw surgery (Le Fort I advancement combined with a mandibular procedure) for severe class III malocclusion, however, two splints are made—an intermediate splint used intraoperatively to position the maxilla in its final position and a final splint to position the mandible.

IMAGING

- Lateral cephalometric radiographs are obtained for cephalometric analysis.
- Panoramic radiographs are obtained to determine the presence and location of mandibular third molar teeth, level of the inferior alveolar canal.
- A submentovertex view of the mandible could be used in determining its shape and flare.
- A CT scan may be obtained, in case virtual surgical planning is undertaken in lieu of traditional model surgery.

DIFFERENTIAL DIAGNOSIS

- Class III skeletal relationship can be due to mandibular prognathism, maxillary hypoplasia, or a combination of both.
- Accurate diagnosis is important to determine the appropriate surgery.
- The diagnosis is confirmed by detailed clinical evaluation combined with cephalometric analysis.

FIG 2 • U-shaped **(A)** and V-shaped **(B)** mandibles as seen in norma basalis. (Courtesy of Myron R. Tucker, DDS, Scientific Liaison, OsteoScience Foundation.)

- Acromegaly and pituitary hyperactivity should be suspected in mandibular prognathism that presents later in life, and appropriate workup is indicated.
- Unilateral hyperplasia of the mandible can cause an asymmetric prognathism and malocclusion. The surgeon should rule out a neoplasm of the mandibular condylar structures in these cases. Unilateral condylar hyperplasia is an idiopathic, rare condition that can also cause an asymmetric mandibular prognathism.

NONOPERATIVE MANAGEMENT

- Mild class III malocclusion can be treated with orthodontic management alone.
- True skeletal class III relationships and asymmetries can be treated only by surgical intervention, however.

SURGICAL MANAGEMENT

- The IVRO setback procedure is usually performed during the late teenage years after the patients have reached skeletal maturity.
- The main objective of the operation is to reduce the horizontal mandibular width that contributes to the prognathism and to reposition the mandible posteriorly to meet the maxilla in a normal class I relationship.

Preoperative Planning

- The risks, benefits, and complications are discussed with the patient on the day of surgery.
- Preoperative photos are obtained for documentation purposes.
- Lateral cephalometric radiographs are obtained for cephalometric analysis.
- Panoramic radiographs are obtained to determine the presence and location of mandibular third molar teeth, level of the inferior alveolar canal.
- A CT scan may be obtained, in case virtual surgical planning is undertaken in lieu of traditional model surgery.

Positioning

- The patient is positioned supine with the arms tucked.
- He or she is intubated nasally, and the endotracheal tube is secured appropriately to the forehead.
- IVRO setback is performed through an intraoral approach.

TECHNIQUES

■ Exposure

- Cleanse the oral cavity with chlorhexidine or an equivalent antiseptic mouth-rinse, and place a throat pack.
- Inject a local anesthetic containing a vasoconstrictor to infiltrate the area of dissection.
- Access to the ramus is obtained through a lateral approach.
- A ramus-exposing incision is made from the level of the occlusal plane to the level of the first molar tooth (**TECH FIG 1A**). An adequate cuff of gingiva (2 to 4 mm) is maintained adjacent to the molar teeth for relaxed wound closure.

- It is important to make this incision in that appropriate position. If the incision is too lateral, it can heal causing a scar band that can cause a pocket that traps food and makes hygiene difficult to maintain, especially during the healing phase.
- A full-thickness mucoperiosteal flap is elevated, exposing the entire lateral border of the ramus of the mandible. This extends from the inferior border of the mandible to the sigmoid notch in that plane.
 - The periosteum along the posterior border of the mandible is left unreleased. There is no exposure on the medial aspect of the mandible.
 - A Bauer retractor is placed in the sigmoid notch, and a second Bauer retractor is placed at the inferior border.
- A variant technique uses a Levasseur-Merrill retractor, which is placed at the posterior border. This, however, requires stripping the periosteum from the posterior border of the mandible (**TECH FIG 1B**).

TECH FIG 1 • **A.** Appropriate incision for exposure of the mandible. **B.** Placement of appropriate retractors and exposure of the lateral ramus.

■ Intraoral Osteotomies

- This is a two-step procedure—first a superior osteotomy and then an inferior osteotomy (**TECH FIG 2**).

Superior Osteotomy

- The exposed lateral border is inspected and the antilingual prominence is

identified.

- The antilingula is not always a reliable indicator of where the lingula would coincide medially. However, staying posterior and inferior to the antilingula places the cuts in a safe zone, avoiding injury to the inferior alveolar neurovascular bundle.
- Using an oscillating saw with an 11.5- × 7-mm blade (**TECH FIG 3A**), the surgeon makes an osteotomy outline approximately a centimeter in front of the posterior border of the mandible.

A

B

TECH FIG 2 • Lateral **(A)** and medial **(B)** views of the two-step osteotomy. Appropriate two-step osteotomy ensures optimal medial pterygoid attachment.

- A curved Freer elevator is placed at the posterior border to approximately measure this distance and to ensure that the marking is in the appropriate position (**TECH FIG 3B**).
- Cuts made anterior to the antilingula or too close to it will damage the mandibular canal and its contents.
- Following confirmation of the position of the cut, the oscillating saw is now used to complete the osteotomy (**TECH FIG 3C**).
- The cutting edge of the blade is first directed toward the sigmoid notch.
- Saw movement should never be forced and is directed with a gentle, back and forth rotational movement of the shaft.
- The bone is thinner as the blade approaches the sigmoid notch, and its depth of insertion should be adjusted accordingly (**TECH FIG 3D**).

Inferior Osteotomy

- The upper Bauer retractor is removed to make the access easier for the inferior part of the osteotomy.
- The inferior cut is made with the same saw blade by directing it inferiorly within the same cut.
- The osteotomy is performed anteriorly and inferiorly below the antilingula, aiming away from the posterior border. This provides a robust proximal segment on completion of the osteotomy.

Mandible Repositioning

- After confirming that the osteotomy is complete along the entire ramus, the mandible is positioned into a class I relationship by separating the proximal segment and moving it lateral to the distal segment (**TECH FIG 4A**). An occlusal splint can be used if needed.
- Final occlusion is established with maxillomandibular fixation (MMF).
- Trim the proximal segment with a round bur to allow passive overlap of the segments.
- Though the IVRO is usually a bilateral procedure, it is occasionally performed only unilaterally to correct minor asymmetries and setbacks. When performed bilaterally, the same steps are repeated on the contralateral side.
- Following ramus osteotomies bilaterally, irrigate the wounds, and suction the oral cavity; remove the throat pack, and establish the planned occlusion, and secure MMF.

- Inspect both osteotomies for lateral overlap and passive positioning of the proximal segment. If the tip of this segment can be palpated in the submandibular area, it needs to be trimmed (**TECH FIG 4B**).
- The wounds are closed with continuous 3-0 chromic in a watertight fashion.

TECH FIG 3 • **A.** Oscillating saw with an 11.5- × 7-mm blade. **B.** A curved Freer elevator is placed at the posterior border of the mandible to approximately measure the distance to ensure the osteotomy is in the appropriate position. **C.** Oscillating saw in position

for the osteotomy. **D.** The bone is thinner at the sigmoid notch.

TECH FIG 4 • A. When the osteotomy is completed, the proximal segment of the mandible is separated and moved laterally to overlap the distal segment. **B.** If the proximal segment is too prominent and is palpable in the submandibular area, it is trimmed.

PEARLS AND PITFALLS

Physical findings

- Class III skeletal relationship can be caused by mandibular prognathism, maxillary hypoplasia, or a combination of both. Accurate diagnosis is critical to determine the appropriate surgery to correct the deformity.
- V-shaped mandibles are better suited for setback using the IVRO technique than are U-shaped mandibles (see **FIG 2**).
- IVRO is better suited for mandibular setbacks in patients with pre-existing TMJ symptoms.
- IVRO has limited application in mandibular advancements.

Technique

- Leaving an insufficient cuff of gingiva when making the incision will lead to difficulty suturing and possible wound dehiscence.

- Too thick a cuff produces a scar band and a pocket for food impaction.
- Marking the osteotomy position behind the antilingula is prudent to avoid the mandibular canal during osteotomy.
- Alternatively, a 30-degree endoscope can be inserted into the wound to inspect the position of the planned osteotomy.
- The saw should be lightly applied and never forced.
- The saw blade may be too long in areas of thinner mandible when approaching the sigmoid notch.
- If the 11.5- × 7-mm blade is too short to complete the osteotomy, there is a good chance that the planned osteotomy is positioned too far anteriorly and likely in the mandibular canal.
- IVRO should not cause mandibular nerve hypoesthesia. If it does, the cuts violated the canal.
- Directing the saw anteriorly and inferiorly while making the cut inferior to the antilingular prominence ensures a robust proximal segment with a good amount of medial pterygoid attachment.
- Angled instruments can be used to rigidly fixate IVRO segments. This is seldom utilized and is generally unnecessary.

POSTOPERATIVE CARE

- The patient is generally extubated in the operating room and taken to recovery breathing spontaneously. However, if there are any airway concerns, the patient may be left intubated and taken to the ICU.
- MMF is left in place for anywhere from a few days to a few weeks, depending on operator preference.
 - Most surgeons prefer MMF for at least a few days following the procedure.⁶
 - Light guiding elastics may be required to help train the occlusion after removal of rigid interdental wiring.

OUTCOMES

- Although IVRO is a reliable technique for mandibular setback and closure of small open bites, it can occasionally be used for mandibular lengthening or counterclockwise rotation of the mandible.
- Stripping of masseter and medial pterygoid can lead to a 14% incidence of open bite at the time of MMF release. This was described as a result of “condylar sag.”
- In general, up to 10 mm of mandibular setback is possible with an IVRO. The magnitude of the setback should not exceed the width of the medial pterygoid

attachment on the proximal segment.

COMPLICATIONS

- Risks from an IVRO include injury to the inferior alveolar and/or lingual nerves, condylar sagging and malpositioning, relapse, bleeding including pseudoaneurysms, infection, and fibrous union.
- Direct injury to the inferior alveolar nerve may occur while making the osteotomies, but an indirect injury can also occur if the proximal segment slips medially and impinges on the nerve bundle.
- Condylar sagging occurs when the muscles are excessively stripped or when the osteotomies create a small proximal segment.
- Significant bleeding can occur if the blade injures the masseteric artery within the sigmoid notch, or larger vessels like the internal maxillary artery or its branches in the medial ramus area. Other potential sources of bleeding are the facial artery and the retromandibular vein. Bleeding can be prevented by careful surgical technique and protection of the soft tissue.
- Wound dehiscence and/or infection are a rare complication and are most often related to poor oral hygiene.

40 Internal Mandibular Distraction

CHAPTER

Michael Alperovich and Roberto L. Flores

DEFINITION

- Mandibular hypoplasia or an underprojected and diminutive mandible can have functional consequences including tongue-based airway obstruction, sleep apnea, reduced intraoral opening, and malocclusion.¹
- Mandibular hypoplasia can also result in facial disharmony and distressing aesthetic concerns.²

ANATOMY

- The normal mandible can be divided into two, symmetric halves from the midpoint of the mandibular symphysis.
- Each hemimandible can be subdivided into several segments: the parasymphysis, body, angle, ramus, and condyle (**FIG 1**).
- The symphysis is the midline of the mandible. The parasymphysis is a region bound by the roots of the mandibular canines. The mandibular body extends from the mandibular canine roots to the mandibular third molar.
- The mandibular angle is the triangular region that represents the junction between the mandibular body and ramus. The mandibular ramus is the vertical component of the mandible extending from the angle to the sigmoid notch.
- The mandibular condyle is the portion of posterior mandible extending cephalad from the sigmoid notch and articulating with the temporomandibular joint.
- The Pruzansky-Kaban classification is widely used to define mandibular deficiency and is most commonly used to classify craniofacial microsomia severity (**FIG 2**).³

FIG 1 • Schematic demonstrating the anatomic subdivisions of the hemimandible.

- A type I mandible features hypoplasia of the mandibular ramus and condyle with a normal mandible morphology.
- A type IIA mandible features reduction in the volume of the body, ramus, and condyle but has a preserved temporomandibular joint.
- A type IIB mandible features reduction in the volume of the body, ramus, and condyle, as well as medial inclination of the ramus displacing the condyle from the glenoid fossa.
- A type III mandible features severe ramus reduction or complete absence with no evidence of a temporomandibular joint.

PATHOGENESIS

- Mandibular hypoplasia has congenital and acquired causes, with congenital causes predominating.
- Craniofacial microsomia and Pierre Robin sequence are the most common congenital causes followed by Treacher Collins syndrome.⁴

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with mandibular hypoplasia secondary to craniofacial microsomia can have malformations in other structures derived from the first and second branchial arches, including the external ear; midface (zygoma and orbit); facial nerve, with the marginal mandibular nerve most commonly affected; muscles of mastication; as well as soft tissue deficiencies.
- Unilateral craniofacial microsomia patients will present with asymmetric facies and an upward occlusal cant on the affected side. The ramus is predominantly affected in craniofacial microsomia.
- In addition to a hypoplastic mandible, Pierre Robin sequence patients fulfill the triad of micrognathia, glossoptosis, and airway obstruction. Retropositioning of the tongue is responsible for airway obstruction and increased work of breathing. Most patients will also present with a U-shaped cleft palate.
- Mandibular hypoplasia in Pierre Robin sequence patients is characterized by bilateral and symmetric mandibular hypoplasia most severely affecting the body.
- Up to 50% of Pierre Robin sequence patients have an associated syndrome, with Stickler syndrome as the most common.⁵
- Pierre Robin sequence patients may present with failure to thrive, feeding difficulties, developmental delay, reflux, carbon dioxide retention, heart failure, and desaturations most pronounced in the supine position.

FIG 2 • Pruzansky-Kaban classification of mandibular deficiency.

IMAGING

- Preoperative imaging should include a craniofacial CT to evaluate mandibular morphology including the TMJ and for planning the ideal vector for

mandibular distraction (**FIG 3**).

- A Panorex may be obtained to evaluate occlusion and identify the location of the unerupted tooth buds but is often not necessary if a CT image is obtained.
- If applicable, dental study models should be obtained for future orthodontic splint fabrication (ie, correction of any resulting open bite and molding the newly generated bone).
- A polysomnogram should be performed to confirm the presence and etiology of sleep apnea.
- Bronchoscopy and endoscopy should be performed to identify other potential causes of obstruction.

DIFFERENTIAL DIAGNOSIS

- Causes of airway obstruction in addition to retrognathia include the following:
 - Adenoid/tonsillar hypertrophy
 - Bronchial stenosis
 - Bronchomalacia
 - Central sleep apnea
 - Laryngomalacia
 - Subglottic narrowing
 - Tracheomalacia

NONOPERATIVE MANAGEMENT

There is no nonoperative management for mandibular hypoplasia. Airway compromise associated with retrognathia can be managed through conservative and invasive techniques.

- Initial conservative techniques include the following:
 - Prone positioning
 - Supplemental oxygen

FIG 3 • Representative craniofacial CT of a patient with Pierre Robin sequence and mandibular body deficiency prior to mandibular distraction.

- Nasopharyngeal tubes
- Continuous positive airway pressure
- Interventional techniques include the following:
 - Intubation
 - Tracheostomy
 - Tongue-lip adhesion
 - Mandibular distraction osteogenesis
- Intubation stabilizes airway management and can be temporizing prior to more definitive approaches.
- Tracheostomy will provide a definitive airway; however, the procedure can lead to tracheomalacia, chronic pneumonia, laryngeal stenosis, complex nursing care needs, and impaired psychosocial development.⁶
- Tongue-lip adhesion provides less relief to the obstructed airway when compared to mandibular distraction. It has been associated with lower oxygen saturation levels and higher apnea-hypopnea indices postoperatively, as well as higher conversion rates to tracheostomy.⁷

SURGICAL MANAGEMENT

Preoperative Planning

- Mandibular distraction has functional indications that include improving lower jaw position and morphology, correcting tongue-based airway obstruction and obstructive sleep apnea, obviating the need for tracheostomy, optimizing the airway for decannulation, treating temporomandibular joint ankylosis, and lengthening a shortened mandible due to trauma or extirpative surgery.
- Mandibular distraction has aesthetic indications to treat facial disharmony or augment a hypoplastic mandible in the absence of a functional deficit.
- If neonatal distraction is considered, patients need to be evaluated by otolaryngology, neonatology, genetics, pulmonology, and a pediatrician prior to surgery.
- If the patient is an older child (non-neonate) or adult, consultation and partnership with a craniofacial orthodontist are recommended.

- In cases in which airway obstruction is a concern, bronchoscopy and laryngoscopy must be performed by an otolaryngologist to rule out secondary airway anomalies (tracheomalacia, subglottic stenosis, tracheal rings).⁸
- Craniofacial CT is used preoperatively to evaluate the mandibular shape, tooth bud position, and course of the inferior alveolar nerve and to plan the distraction vector.
- Polysomnography preoperatively can help differentiate between central and obstructive sleep apnea, establish a baseline apnea-hypopnea index, and confirm retention of carbon dioxide.⁹

Positioning

- The patient is positioned supine, endotracheally intubated, and placed on a horseshoe for maximal maneuverability of the craniofacial region.
- The entire face and neck are prepped into the field.

Approach

- Extraoral and intraoral approaches have been described. Only the extraoral approach will be described below.
- External and internal distraction devices are used, but this chapter will exclusively focus on internal distraction devices.¹⁰

TECHNIQUES

■ Internal Mandibular Distractor Placement

- Mark a Risdon incision parallel and 2 cm inferior to the mandibular body. This distance can be shortened to 1 cm in neonates (**FIG 4**).
- Inject weight-based local anesthetic along the planned skin incision; avoid anesthetic toxicity in the pediatric population.
- Incision and dissection are extended sharply through skin, subcutaneous tissue, and platysma. Superior and inferior platysmal flaps are raised to provide a tension-free, layered final skin closure.
- Be vigilant to remain inferior to the marginal mandibular nerve; if the nerve is identified during dissection, it is carefully protected.
- Preoperative craniofacial CT imaging informs the type and location of the

osteotomy as well as the distraction vector. These factors influence the type of exposure required. Although there is no consensus on the optimal osteotomy type, the most popular are body, ramus, inverted L, and transport distraction.

- The periosteum is identified and incised along the inferior border of the mandibular body. Subperiosteal dissection is extended across the entire buccal surface of the mandible from the proximal ramus through the distal body. This includes exposure to the coronoid and sigmoid notch if an inverted-L osteotomy is considered (**TECH FIG 1A**).

FIG 4 • Risdon incision drawn on a neonate. The chin is to the left. The ear is superior and to the right. Note the incision may be drawn 1 cm below the mandibular border in neonates.

- If the mandibular deficiency is predominant in the body, the inverted-L osteotomy is favored. Alternatively, a transverse mandibular body, mandibular angle, or transverse ramus osteotomy can also be used (**TECH FIG 1B**).
- For the inverted-L osteotomy, a near-complete vertical ramus osteotomy is performed from the sigmoid notch to the antegonial notch. Coronoidectomy is performed using a sagittal saw or Kerrison punch (**TECH FIG 1C**).

- A full corticotomy is performed over the buccal surface and the cephalad and caudal margins of the lingual surface. A bony bridge in the center of the lingual surface of the mandible is maintained to preserve mandibular alignment during distractor placement (**TECH FIG 1D**).
- If the mandibular deficiency is predominant in the ramus as is commonly seen in Treacher Collins syndrome, a vertical distraction vector is utilized. This osteotomy may risk injury to the temporomandibular joint and cause ankylosis of the joint.
- A semiburied distraction device is affixed to the lower border of the mandible (if a horizontal vector is used) with the activation arm exiting behind the earlobe. The maximum distraction length is determined on a case-by-case basis with 20 mm favored in infants and 30 mm in older children or for cases of severe mandibular deficiency.
- High-profile screws are used to secure the distraction device for ease of removal after consolidation (**TECH FIG 1E**).
- After the device is secured, it is activated for several millimeters to confirm the absence of resistance. The lingual surface osteotomy is often completed with device activation alone. Complete osteotomy is confirmed using an osteotome or suction cannula.
- Prior to soft tissue closure, the bony edges are returned to apposition and any intervening soft tissue is removed.
- The platysma muscle is reapproximated using resorbable suture followed by closure of the dermis and epidermis.

TECH FIG 1 • A. Wide subperiosteal dissection is needed to perform an inverted “L” osteotomy. This includes the distal body, the angle, the ascending ramus, and sigmoid notch. If a mandibular body osteotomy is planned, less undermining is required. **B.** Inverted “L” osteotomy is drawn. Note the vertical osteotomy extends from the sigmoid notch to the

antegonial notch. **C.** Coronoidectomy can be performed with a sagittal saw or Kerrison punch. **D.** The inverted-L osteotomy is made to near completion with preservation of the lingual cortex just superior to the mandibular border and inferior to the sigmoid notch. This narrow bony bridge will maintain anatomic bony position, while the hardware is placed. Completion osteotomy is performed after the hardware is secured. **E.** High-profile screws may be used to facilitate placement and removal of hardware.

■ Internal Mandibular Distractor Removal

- Remove the distraction device 8 weeks following consolidation.
- Use the prior Risdon incision to access the device while remaining vigilant of the course of the marginal mandibular nerve and raising platysmal flaps to maintain a tension-free skin closure.
- Assess the integrity of the generated bone across the distracted segment by visual inspection and manual palpation.
- Removing the device is easiest when the minimum number of high-profile screws is used initially.
- As with device placement, reapproximate the platysma muscle first followed by the dermis and epidermis.

PEARLS AND PITFALLS

Incision

- At the start of the procedure, raise supraplatysmal skin flaps to close the platysma muscle as a deeper layer separate from the skin. Removing tension from the skin closure can improve long-term scar appearance.

Warning

- In neonatal distraction, the mandibular bone can be very soft. Gently incise the periosteum with a 15 blade or when using an elevator as both instruments can damage the outer cortex.
-

Technique	■ If using an inverted-L osteotomy, the inferior mandibular osteotomy should be planned posterior to the antegonial notch to avoid tooth buds.
Implant burden	■ Minimize the number of high-profile screws placed to secure the distractor (four per side) for easier distractor removal after consolidation.
Theory	■ Premature consolidation is more commonly a result of incomplete lingual corticotomy. Test the distractor, and confirm the absence of any resistance before completion of surgery.
Therapeutic success	■ When performing mandibular distraction to improve the airway, serial cephalograms and a repeat polysomnogram should be performed 3 months after completion of distraction.

POSTOPERATIVE CARE

- A latency period of 5 days is routinely used followed by activation at a rate of 1 mm/d.
- Serial cephalograms are used to monitor progress with device removal following 8 weeks of consolidation.
- If distraction has been performed to relieve airway obstruction, a follow-up polysomnogram should be performed.
- In neonatal patients, mandibular distraction can prevent tracheostomy. In chronically tracheostomy-dependent patients, mandibular distraction can result in decannulation of the tracheostomy.
- Overcorrection of the mandible is advised when distraction is performed in a skeletally immature patient with some studies advocating 40% to 50% overcorrection.¹¹

OUTCOMES

- Mandibular distraction has a success rate of 92% to 100%.¹²
- Risk factors for failure of mandibular distraction in Pierre Robin sequence include GERD, need for Nissen fundoplication, and absence of a cleft palate.¹²

COMPLICATIONS

- Major complications
 - Marginal mandibular nerve injury
 - Inferior alveolar nerve injury
 - Tooth bud injury

- Temporomandibular joint ankylosis
- Death
- Moderate complications
 - Device failure or fracture
 - Premature consolidation/incomplete osteotomy
 - Device exposure
 - Pin dislodgment
 - Fibrous nonunion
 - Dentigerous cysts secondary to distraction across a tooth follicle
- Minor complications
 - Marginal mandibular nerve neurapraxia
 - Pin-tract soft tissue infection
 - Unfavorable scars

41 External Mandibular Distraction for Micrognathia

CHAPTER

Haithem M. Elhadi Babiker

DEFINITION

- Distraction osteogenesis of the craniofacial skeleton was first attempted by Snyder in 1972.
- In 1991, McCarthy et al. published their experience with mandibular distraction, popularizing the technique.¹
- Mandibular distraction osteogenesis (MDO) can be performed with either an external or internal technique. Both techniques have been proven to be successful and safe to lengthen the mandible.²
- External mandibular distraction involves making a mandibular osteotomy and applying an external device to slowly and gradually lengthen the mandible. This technique is used to lengthen the hypoplastic mandible seen in multiple craniofacial conditions.

ANATOMY

- The mandible is a unique U-shaped bone with two vertical rami and a horizontal body. It articulates with the skull at the temporomandibular joints and is the only movable bone of the facial skeleton.
- The inferior alveolar nerve enters the mandibular foramen on the medial aspect of the ascending ramus and then extends within the mandibular body, exiting at the mental foramen.
- The lingual nerve is located medial to the ramus in close proximity to the alveolar process near the third molar.

FIG 1 • **A.** CT scan showing the bilateral micrognathia in Pierre Robin sequence (PRS). **B.** Patient with hemifacial microsomia (HFM) demonstrating severe micrognathia. **C.** Patient with Treacher Collins syndrome (TCS) exhibiting severe micrognathia (both mandibular body and ramus), and an anterior open bite.

- Patients with Pierre Robin sequence (PRS) are characterized by a hypoplastic mandibular body; the condyle and ramus are generally of normal size (**FIG 1A**).³
- Hemifacial microsomia (HFM) is usually unilateral and is classified using a spectrum of severities from type I to type III (**FIG 1B**).
- In Treacher Collins syndrome (TCS), the hypoplasia is similar to that seen in PRS but also includes a deep antegonial notch and downslanting mandibular body (steep occlusal plane) associated with an open bite. Some TCS mandibles may exhibit features similar to HFM (**FIG 1C**).⁴
- Post-traumatic condylar fractures may also lead to mandibular hypoplasia associated with bilateral TMJ ankylosis.

PATHOGENESIS AND HISTORY

- Mandibular hypoplasia occurs either as an isolated condition (possibly due to intrauterine physical growth restriction) or as part of a genetic abnormality.
- Patients with mandibular hypoplasia present most commonly during the neonatal period due to obstructive sleep apnea (OSA).
- HFM is the second most common craniofacial congenital anomaly, with an incidence of 1/3000 live births.

- Once a child is born with mandibular micrognathia, the deformity is not progressive.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with micrognathia usually present during infancy with tongue-based OSA, ranging from mild to very severe.²
- The small mandible pushes on the tongue causing it to fall back and obstruct the airway.
- Mild cases present with noisy breathing during sleep.
- More severe cases present with apneic episodes, cyanotic spells, and feeding abnormalities.⁵
 - The child expends most of his or her energy trying to breathe, and hence has no energy to feed.
 - Poor weight gain and failure to thrive are strong indicators of severe OSA.⁶
- Neonates with severe OSA require urgent admission to the neonatal intensive care unit (NICU) for airway stabilization.
 - Treatment modalities include prone positioning, nasopharyngeal airway, tongue-lip adhesion, and in very severe cases, tracheostomy.
- The main objective of mandibular distraction is to avoid a tracheostomy or to achieve decannulation in patients with a tracheostomy.

IMAGING

- Lateral cephalometric radiographs can be used to identify the mandibular micrognathia. In neonates, a lateral skull x-ray at a distance of 72 in. is used to evaluate the hypoplastic mandible.
- The best imaging modality is a three-dimensional computed tomography (3D CT) scan to characterize the mandible and to render a volumetric measurement of the airway.
 - Low-dose CT scans use very low radiation (comparable to traditional radiographs) without compromising image quality (**FIG 2**).

DIFFERENTIAL DIAGNOSIS

- HFM, 1:3000 live births
- PRS, 1:14 000⁷
- TCS, 1:50 000 live births⁸
- Nager syndrome
- Post-traumatic condylar fractures

- Stickler syndrome, velocardiofacial syndrome, fetal alcohol syndrome, trisomy 21 and 22, and Kabuki syndrome⁹

FIG 2 • CT scan showing mandibular micrognathia, retropositioning of the tongue, and narrow airway stripe.

NONOPERATIVE MANAGEMENT

- Prone and lateral decubitus positioning.
- Nasopharyngeal airway, oxygen support, and possible tongue suture.¹⁰
- ICU care and close monitoring is critical to prevent rapid deterioration.
- A multidisciplinary team comprised of neonatology, otolaryngology, pulmonology, plastic surgery, and genetics should make the decision regarding treatment planning.
- The infant is evaluated with a polysomnography and a microlaryngoscopy/bronchoscopy, which examines the entire airway and differentiates lower airway from upper airway problems.
- Mild cases are treated with conservative measures.

SURGICAL MANAGEMENT

- Tongue-lip adhesion is advocated by some centers with variable success.^{6,11}
- Tracheostomy remains the standard in very severe cases of OSA.^{8,11}
- Mandibular distraction is generally undertaken during the neonatal period.
- The main objective of the operation is to lengthen the mandible, which pulls

the tongue forward to relieve the tongue-based respiratory obstruction.

- The main steps of the surgery are as follows:
 - Intraoral incision(s) to expose the posterior aspect of the mandible.
 - Saw or bur to make a corticotomy in the ascending ramus/angle of the mandible.
 - Self-drilling pins into the mandible proximal and distal to the corticotomy site.
 - If a rigid external distraction (RED) device is used, place the anterior mandibular plate and secure it to the mandible with monocortical screws.
 - Use a 5-mm osteotome to convert the corticotomy into an osteotomy to completely liberate the mandibular segments.
 - Attach the distraction device to the pins.
 - If an RED is used, attach the halo component to the anterior mandibular plate using 25-gauge wire.
 - Close the intraoral wound in watertight fashion.
 - Wait 1 to 3 days (latency period) and then activate the device (activation period) until the desired final position of the mandible is achieved.
 - Maintain the device in position until the new bone mineralizes (consolidation period).
 - Remove the distraction device at the end of the consolidation period.
- The operation is performed bilaterally in cases of PRS, TCS, and Nager syndrome; or unilaterally in cases of HFM.
- Selection criteria for mandibular distraction include severe mandibular micrognathia (maxillomandibular differential of greater than 8 mm), polysomnogram showing severe OSA, and difficulty with breathing and feeding.⁸

Preoperative Planning

- A 3D CT scan is obtained to delineate the morphology of the mandible, the position of the inferior alveolar nerve and the teeth follicles.
- Cephalometric measurements can be obtained from the CT scan to quantify the mandibular hypoplasia.

Positioning

- The patient is positioned supine.
- The procedure is generally performed in conjunction with ENT and pulmonology to perform the MLB and assist with intubation.

- The procedure is done under general anesthesia.
- The patient is intubated nasally; the endotracheal tube is sutured to the nasal septum and secured appropriately to the forehead (**FIG 3**).
- A foam donut stabilizes the head.

Approach

- Surgery is performed through an intraoral approach with percutaneous placement of the pins.

FIG 3 • Endotracheal tube secured to the forehead and sutured to the nasal septum.

TECHNIQUES

■ External Mandibular Distraction With Pins

Exposure and Dissection

- Inject local anesthetic with vasoconstrictor to infiltrate the area of dissection in the posterior mandible.
- Insert a bite block/gauze sponge on the opposite side of dissection to adequately open the mouth.

- Expose the area of dissection by placing two Langenbeck retractors to pull away the cheek.
 - In very small babies, malleable retractors can be used instead. Place a tongue retractor to protect the tongue.
- A 3-cm incision is made in the area of the ascending ramus and angle of the mandible.
- Sharp dissection is carried through mucosa, muscle, and periosteum to raise a full-thickness mucoperiosteal flap exposing the entire ascending ramus and posterior body of the mandible (**TECH FIG 1**).
- Dissection is also performed on the lingual aspect of the ramus, while protecting the inferior alveolar nerve.
- A malleable retractor is inserted on the medial aspect of the ramus to retract and protect the neurovascular bundle.

Corticotomy

- Using an ultrasonic saw (**TECH FIG 2A**) or a reciprocating saw, a corticotomy is made at the angle of the mandible.

TECH FIG 1 • Exposure of the posterior aspect of the mandible. 1: Arrow pointing to the angle of the mandible.

- The site of the osteotomy is determined from the CT scan to avoid the teeth

follicles.

- The direction and orientation of the osteotomy determines the desired vector of distraction. Distraction can occur in the horizontal, vertical, or oblique direction (depending on the relationship of the vector to the long axis of the mandibular body).¹²
 - A horizontal vector along the long axis of the mandible will lengthen the mandible in a purely horizontal plane. This is the case of bilateral micrognathia seen in PRS and TCS patients where most of the deficiency is in the mandibular body.
 - A vertical vector of distraction is preferred for lengthening a deficient ramus in a vertical direction as seen in HFM.
 - An oblique vector simultaneously lengthens the body of the mandible and elongates the ramus.
- The corticotomy extends from the alveolar process to the inferior border of the mandible, where the bone is thicker (**TECH FIG 2B**).
 - The thick inferior mandibular border must be completely cut to prevent a bad split of the mandible (**TECH FIG 2C**).

Pin Placement

- The site of pin placement is determined based on the angle and orientation of the osteotomy, and the location of tooth follicles.
- One or two self-drilling and self-tapping pins (40 mm long) are then placed percutaneously proximal to the corticotomy (**TECH FIG 3A**).
- A stab incision is made in the skin immediately below the inferior border of the mandible to gain access to the bone, and the pins are screwed into the bone using a manual pin driver (**TECH FIG 3B**).
 - Ensure that the pins are perpendicular to the bone and advanced far enough into the bone to engage both cortices (**TECH FIG 3C**).
- The skin immediately anterior to the proximal pin/s is retracted posteriorly, and one or two more pins are drilled distally in a similar fashion. Retraction of the skin creates redundancy and allows stretching as distraction progresses and minimizes the scar.
 - The pins are placed parallel to each other with a distance of 3 cm between them (**TECH FIG 3D**).

TECH FIG 2 • **A.** Ultrasonic saw. **B.** The desired vector of distraction determines the site and orientation of the osteotomy. **C.** Osteotomy extends along the entire height of the mandible and must ensure that tooth follicles are avoided.

- Another option is to use two long pins (120 mm) to penetrate both sides of the mandible for added stability (transfixed pins; **TECH FIG 3E,F**).

Placement of the Distraction Device

- A 5-mm osteotome completes the osteotomy to liberate the two segments of the mandible (**TECH FIG 4A**).
- The intraoral wound is closed with absorbable sutures in a watertight

fashion.

- The distraction device is then attached to the pins and adjusted using the activator screwdriver (**TECH FIG 4B–D**).
- A uniplanar or multiplanar distraction device can be used depending on the desired end point of distraction (**TECH FIG 4E–G**).

TECH FIG 3 • **A.** Self-drilling, self-tapping percutaneous pins. **B.** Manual screwdriver is used to drive the pins percutaneously into the mandible. **C.** Percutaneous pins are placed perpendicular to the bone and advanced far enough to engage both cortices. **D.** Pins are placed parallel with about 3 cm distance between them. **E.** Long percutaneous pin (120 mm). **F.** The transfixated pin traverses both sides of the mandible.

TECH FIG 4 • **A.** Osteotomy of the mandible. **B.** Distraction devices of 30 and 45 mm showing the slots for engaging the pins. **C.** Distractor device connected to the pins. **D.** Activation driver is used for both activating the device and securing the pins to the distractor. **E.** Uniplanar distractor with the activation arm emerging anteriorly. **F.** Uniplanar distractor with the activation arm emerging posteriorly toward the ear. **G.** Multiplanar distractor that can lengthen both the body and ramus of the mandible.

■ External Mandibular Distraction With Rigid External Device

- If a RED device is used instead of the pin technique, the same initial steps are followed.
- After creation of the corticotomy, the anterior mandibular retention plate is secured to the menton of the mandible (**TECH FIG 5A**).
- A small stab incision is made in the buccal vestibule below the lower mandibular incisors.
 - A 2-mm Steinmann pin is advanced through this incision in an intraoral to an extraoral direction to exit through the skin of the chin and create a passage for the plate (**TECH FIG 5B**).
 - Ensure that the most anterior portion of the symphysis is captured with the pin so that the plate rests within a groove in the mandible for added stability.
- The T-shaped plate (1.5 mm thickness) is then inserted to follow the passage created by the pin and exits through the skin (**TECH FIG 5C**).
 - The plate is bent and adapted to conform to the anterior part of the mandible overlying the mucosa (**TECH FIG 5D**).
- Self-drilling screws are then drilled transmucosally using a cordless driver to secure the plate to the mandible.
 - Three screws (7 mm in length) are used per side (**TECH FIG 5E**).
- The free end of the plate is then bent upward, and a wire loop is inserted through it (**TECH FIG 5F**).
- The halo of the RED device is then applied to the skull using a minimum of three fixation screws per side (**TECH FIG 5G**).
- Ensure that the halo is parallel to the Frankfort horizontal.
- After wound closure, the halo is secured to the retention plate using 25-gauge stainless steel wire, which is passed from the slidable loop and through the eyelet of the activation spindle attached to the horizontal crossbar assembly.
 - The wire is then twisted securely (**TECH FIG 5H,I**).

PEARLS AND PITFALLS

Physical findings

- Mandibular micrognathia most commonly presents during the neonatal period due to obstructive sleep apnea.
- There is a wide range of severity; clinical correlation is critical to select the appropriate candidates for distraction.
- Successful mandibular distraction can alleviate the airway obstruction and avoid a tracheostomy.

Technique

- Careful tissue handling is critical in the neonate due to the delicate anatomy.
- Selection of the osteotomy site and pin site is crucial to avoid injury to the tooth buds and the alveolar neurovascular bundle. Radiographic imaging assists to locate the tooth buds.
- Orientation and location of the osteotomy is chosen based on the region of the mandible desired to be lengthened. A vertical vector is chosen in cases of HFM to lengthen the ramus; a horizontal vector is required in bilateral micrognathia seen in PRS and TCS. Multidirectional distraction can be used in select cases.
- Ensure complete liberation of the proximal and distal mandible segments.
- Use of the ultrasonic saw has the added advantage of avoiding injury to tooth follicles and the neurovascular bundle.
- Pins must be placed bicortically or they will dislodge.
- Ensure that the pins are parallel.
- Advantages of the RED device over pin technique:
 - Less risk of damaging tooth buds
 - Less load on the temporomandibular joints
 - Greater length of distraction
- Main disadvantages:
 - Bulkiness that is cumbersome and less accepted socially
 - Inability to use in neonates
 - Multiple components of the RED device make hardware failure more common requiring return to the operating room.
 - An anterior open bite usually results from mandibular distraction,

and this can be particularly problematic in older patients. A “jaw bra” can be used in neonates to minimize the open bite and assist with feeding.¹³

- Postoperative**
- After 6–7 days of distraction, the mandible is lengthened sufficiently to improve the airway and allow extubation.
 - The neonate is monitored in the NICU to prevent airway compromise.
 - The consolidation period is generally twice the activation period. Prolonged consolidation theoretically leads to reduced relapse, but at the expense of feeding difficulty.

POSTOPERATIVE CARE

- The neonate is transferred to the NICU intubated.
- Distraction activation is started on the day after surgery and proceeds at a rate of 2 mm/d.⁸
 - The frequency of distraction is generally twice daily.
 - A pin driver is used for turning the activating arms (two turns of 360 degrees correspond to 1 mm distraction) (**FIG 4A**).
- After 1 week of activation, the mandible is advanced sufficiently to allow safe extubation of the infant.
 - ENT is present to perform microlaryngoscopy/bronchoscopy, which determines the safety of extubation.
- Distraction is then continued at 1 mm/d because the skin tension has reached its maximum at this point. Continued distraction at 2 mm may exceed skin elasticity and lead to wound breakdown.
- In older children, distraction is usually started after a 3-day latency period and the rate is 1 mm/d.
- Pin sites are washed daily with soap and water followed by topical antibiotic ointment. The skin surrounding the pins appears red and stressed, but infection is rare.
- Weekly radiographs are obtained to monitor the progress of distraction and hardware stability.
- The end point of distraction is determined clinically with the aid of serial radiographs to determine the position of the mandible and quantify the airway improvement (**FIG 4B**).
 - The mandible is lengthened to a point anterior to the maxilla (slight class III

occlusion) in anticipation of minor relapse (**FIG 4C**).¹⁴

- Distraction is generally completed within 3 to 4 weeks. The device is left in place for an additional 6 to 8 weeks to complete consolidation.
- At the end of consolidation (radiographic evidence of mineralization), the pins (or the RED device) are removed under sedation in the operating room.
- In older children or teenagers, orthodontic elastics may be used during the activation or consolidation phase in an attempt to close the anterior open bite created during the distraction process.
- Feeding is resumed normally following surgery but may become increasingly difficult as the mandible is advanced. A nasogastric tube is generally needed to aid with feeding and is removed at the end of distraction.

OUTCOMES

- Mandibular distraction is effective in the treatment of airway obstruction associated with micrognathia.¹⁵ Given the high success rate with minimal complications, it has become the standard of care for neonatal OSA (**FIG 5A–E**).
- The procedure should be performed by a surgeon experienced in craniofacial distraction, with the help of a multidisciplinary team.
- The objective of mandibular distraction is to avoid tracheostomy or achieve decannulation in patients who have previously received a tracheostomy. The cost-effectiveness is clearly in favor of MDO over tracheostomy with less morbidity.¹⁶
- Patients with isolated PRS (nonsyndromic) generally require one mandibular distraction procedure to clear the airway. Predictors for repeat distraction include a syndromic diagnosis like TCS, Nager syndrome, Goldenhar, and Stickler syndrome.⁸

FIG 4 • A. Driver engaging the distractor arms and turning. **B.** Bedside radiograph demonstrating advancement of the mandible and improvement of the airway. **C.** A neonate at the time of distractor removal demonstrating overcorrection of the mandible.

FIG 5 • A. Preoperative sagittal view CT scan demonstrating mandibular micrognathia and narrow airway. **B.** Airway improvement at the end of distraction, showing overcorrection. **C.** Two-year postoperative view demonstrating relapse, but with maintenance of airway clearance. **D.** Three-dimensional CT scan before distraction. **E.** Extent of mandibular advancement at the end of the distraction.

- In patients with underlying neurological problems and low muscle tone, MDO generally has a lower success rate. Careful team discussion should precede distraction in this patient population.^{2,6,8}

COMPLICATIONS

- Injury to the inferior alveolar nerve or the tooth buds from inaccurate selection of osteotomy site or pin placement.
- Temporomandibular joint ankylosis due to overloading of the TM joints. This occurs less frequently with the internal technique than with the external technique.
- Infection is a rare occurrence. Pin site infections can be treated with local wound care.
- Pin dislodgement is a common complication. Use of transfixion pins that penetrate both sides of the mandible offers better stability.¹⁷
- Hardware failure and screw loosening is common with use of the RED device.
- Permanent scars from percutaneous pin placement and skin stretching during distraction (**FIG 6**).
 - These scars are generally well accepted by parents and preferable to tracheostomy scars.
- Anterior open bite is a common complication and can be problematic for feeding.
- Relapse is expected; slight overcorrection at the time of distraction is advised (see **FIG 5B,C**).
- Failure of distraction resulting in conversion to tracheostomy is seen in severe cases of OSA. Predictors of failure include PRS without a cleft palate, gastroesophageal reflux, and the need for Nissen fundoplication.¹¹
- Early consolidation may occur if the rate of distraction is too slow, requiring a return to the operating room to repeat the osteotomies.

FIG 6 • Acceptable appearance of the scars 2 years after distraction.

42 External Transfacial Mandibular Distraction

CHAPTER

Brian S. Pan

DEFINITION

- Neonates with tongue-based airway obstruction encompass a heterogeneous group of patients, the most common of which are those with isolated Pierre Robin sequence (PRS).
- Initially described in 1923, patients with PRS share a triad of signs that are micrognathia, glossoptosis, and upper airway obstruction.¹
- The clinical strategies employed to treat these patients are (a) bypassing the tongue base, (b) repositioning the soft tissues to alleviate the obstruction, (c) and correcting micrognathia, the anatomic source of the obstruction.
- Since the original description of mandibular distraction, both internal and external approaches have been demonstrated to be safe and effective options.
- The approach outlined herein includes further modifications to techniques originally described by McCarthy² and Denny.³

ANATOMY

- The mandible is a unique bone composed of vertical and horizontal elements that form a U-shaped construct.
- The typical growth pattern of the pediatric mandible occurs in a superior and posterior direction resulting in a downward and forward displacement of the mandibular body and symphysis.⁴
- From infancy through adolescence, the inferior alveolar nerve migrates superiorly from the lingual, inferior border of the mandible to a more superior position.
- The primary morphological difference between the hypoplastic mandible in PRS and the normal mandible is a small mandibular body. The ramus and

condyles tend to be of normal size.⁵

PATHOGENESIS

- The incidence of PRS is difficult to define but is thought to be more frequent than 1:14 000.⁶
- Micrognathia is hypothesized to be the result of either a genetic growth abnormality or a physical growth restriction.
 - Mandibular hypoplasia may be an isolated problem or related to a craniofacial syndrome, the most common of which are Stickler syndrome, velocardiofacial (VCF) syndrome, fetal alcohol syndrome (FAS), Treacher Collins syndrome (TCS), Nager syndrome, hemifacial microsomia (HFM), trisomy 21 and 22, and Kabuki syndrome.⁷
 - Intrauterine growth restriction causing head flexion, secondary to multiple births, or oligohydramnios is also thought to limit mandibular growth.⁸

PATIENT HISTORY AND PHYSICAL FINDINGS

- Neonates with tongue-based airway obstruction present along a spectrum of severity.
- Those patients with mild to moderate micrognathia may exhibit sonorous breathing during sleep, apneic events, feeding difficulties, and poor weight gain.
- Neonates with more significant micrognathia not only will present with the aforementioned signs and symptoms but may be in severe respiratory distress and appear cyanotic. Sternal and suprasternal retractions and the use of accessory muscles to breathe may also be apparent.
 - In such cases, urgent admission to a neonatal intensive care unit to stabilize the airway is indicated.
- In addition to a small mandible, glossoptosis is observed with a posteriorly positioned tongue that collapses into the pharynx.
- Patients with mild to moderate symptoms may fail to thrive due to the work of breathing during sleep and while feeding.
- The increased negative pressure required to inhale may also result in reflux and aspiration of the gastric contents.⁹

IMAGING

- A lateral cephalogram appropriately evaluates the hypoplastic mandible. The degree of maxillomandibular discrepancy and the posterior airway space can

also be measured.

- A three-dimensional computed tomography scan (3DCT) may also be performed to further characterize the mandible and assess the location of the inferior alveolar nerve and mental nerve foramina.

DIFFERENTIAL DIAGNOSIS

- Although this diagnosis is typically made based on clinical findings and physical examination, a genetic evaluation is an important component of the multidisciplinary management of these patients.
 - This evaluation establishes an accurate diagnosis and anticipates future medical needs if a syndrome is also present.

NONOPERATIVE MANAGEMENT

- Prone and lateral decubitus positioning are the core maneuvers to assist with airway patency while the child is awake and sleeping.
- The use of tongue sutures, nasopharyngeal airways, palatal obturators, and mandibular traction have also been described as effective conservative measures. Their efficacy has been reported to be between 33% and 69% in their respective patient populations.¹⁰
- If long-term conservative care is indicated, close observation and a capable caregiver are critical. Excess movement, coughing, and swallowing can easily displace many of these devices leading to gagging, reflux, aspiration, and potential loss of airway.

SURGICAL MANAGEMENT

- The decision to operate is based upon the consensus of a multidisciplinary team composed of representatives from neonatology, pulmonology, otolaryngology (ENT), genetics, and plastic surgery.
 - In addition to the facial CT, a polysomnogram and direct evaluation of the airway (microlaryngoscopy, bronchoscopy, or nasopharyngoscopy) are typically obtained to aid in decision-making.
- The main objective of the operation is to lengthen the mandible, thereby advancing the attached soft tissues anteriorly, relieving the tongue-based airway obstruction.
- The main steps of the procedure include the following:
 - Expose the mandibular body, angle, and coronoid process bilaterally through intraoral incisions.

- Pass the first transfacial Steinmann pin caudal to the coronoid processes.
- Pass the second transfacial pin just dorsal to the menton.
- Perform bilateral mandibular osteotomies using an ultrasonic osteotome.
- Apply external distractors.
- The patient typically remains intubated following surgery and is transferred to the NICU for postoperative management.

Preoperative Planning

- Risks, benefits, and realistic expectations are discussed with parents prior to surgery.
- Risks include pin migration, tooth damage, injury to the inferior alveolar and mental nerves, bony relapse, scarring, and the possible need for tracheostomy.
- The operation is coordinated with ENT who will assist the anesthetist with nasotracheal intubation if poor visualization of the larynx is anticipated.

Positioning

- The patient is placed in a supine position with several small towels serving as a shoulder roll.
- A foam donut should be used to stabilize the head.
- The nasotracheal tube is sutured to the septum to prevent inadvertent extubation during the operation (**FIG 1**).

FIG 1 • A foam donut is used to stabilize the head. The nasotracheal tube is sutured to the septum to prevent extubation.

TECHNIQUES

■ Exposure

- Lidocaine with epinephrine is infiltrated into the lingual and buccal tissues overlying the dorsal mandibular bodies, angles, and along the ascending ramus.
- Exposure is achieved with a notched ramus retractor and a toe-in Obwegeser. An incision is made over the ascending ramus and extended along the buccal mandibular body (**TECH FIG 1A**).
- Subperiosteal dissection is performed with a Freer elevator, exposing the buccal surface of the mandible to identify the coronoid process, the ascending ramus, the mandibular angle, and the body.
- The lingual surface of the ascending ramus is then exposed to protect the inferior alveolar nerve (**TECH FIG 1B**).

TECH FIG 1 • A. A notched ramus retractor and a toe-in Obwegeser are used to provide exposure. An incision is made over the ascending ramus and extended along the buccal mandibular body. **B.** The buccal surface of the coronoid process, the ascending ramus, the mandibular angle, and the body are exposed. The lingual surface of the ascending ramus is then exposed to protect the inferior alveolar nerve.

■ Pin Passage

- A 25-gauge needle is passed through the cheek to identify the most direct path to the coronoid process (**TECH FIG 2A**).
 - This step is important to avoid traction on the skin from the Steinmann pin, and the resultant scarring that may occur.
 - The site is then marked.
- A 2-mm Steinmann pin is passed transmurally through the cheek into the mandible just inferior to the coronoid process (**TECH FIG 2B**).
- The pin is passed through the buccal mucosa, dorsal to the maxillary tuberosity and caudal to the palate. The pin is advanced transorally and through the contralateral side (**TECH FIG 2C,D**).
 - The ends of the pin are then protected.
- The skin immediately dorsal to the menton is retracted cranially, and the second Steinmann pin is inserted into the mandible through the floor of the mouth, exiting the contralateral side (**TECH FIG 2E**).
- This pin must be kept dorsal to the menton to avoid the mental foramina.
 - The pin should be placed close to the inferior edge of the mandible to avoid the tooth roots but at least 2 to 3 mm above the inferior border to prevent pin migration through the bone (**TECH FIG 2F**).

TECH FIG 2 • **A.** A 25-gauge needle is passed through the cheek to identify the most direct path to the coronoid process. **B.** A 2-mm Steinmann pin is passed through the cheek into the mandible inferior to the coronoid process. **C.** The pin is then passed through the buccal mucosa, dorsal to the maxillary tuberosity and caudal to the palate. The pin is advanced transorally and then through the contralateral side. **D.** Note the hemi-uvulae superior to the Steinmann pin. **E.** The skin just dorsal to the menton is then gently retracted cranially, and the second Steinmann pin is then inserted into the mandible exiting the contralateral side. **F.** The inferior pin should be dorsal to the menton and avoid the mental foramina. The pin should be placed close to the inferior edge of the mandible to avoid the tooth roots. Note the superior pin placement in relation to the coronoid process.

■ Osteotomy and Completion

- The skin on the contralateral side is also retracted cranially. The purpose of this maneuver to prevent traction on the soft tissue and scarring as the mandible is distracted.
- The notched ramus retractor is then placed at the level of the coronoid process, followed by a thin insulated ribbon retractor placed on the lingual aspect of the mandible to protect the inferior alveolar nerve.
 - A toe-out Obwegeser is placed on the buccal aspect of the mandible to expose the mandible for the osteotomy.
- The osteotomy is then made using an ultrasonic osteotome and assessed for completeness with a traditional 5-mm osteotome (**TECH FIG 3A**).
- The external distractors are applied. The distractors are not advanced and are set in a position that maintains the length of the native mandible.
- The pins are then clipped (**TECH FIG 3B**).
- The intraoral incisions are closed with dissolvable suture.

TECH FIG 3 • **A.** The osteotomy is performed similar to a sagittal osteotomy below the level of the cranial pin. It is initiated along the oblique ridge. A thin insulated ribbon retractor should be used to retract the lingual soft tissues and inferior alveolar nerve. **B.** The external distractors are applied. The distractors are not advanced and are set in a position that maintains

the length of the native mandible.

PEARLS AND PITFALLS

Physical findings

- Neonates with tongue-based airway obstruction present along a spectrum of severity.
- Feeding difficulties and poor weight gain in neonates with mild micrognathia may indicate clinically significant obstructive sleep apnea.

Technique

- Steinmann pin placement is critical to avoid injury to tooth buds, inferior alveolar and mental nerve, and to avoid pin migration through the adjacent skin and mandibular border.

Postoperative

- Postoperative extubation is typically safe within 3–5 d following surgery depending on the degree of micrognathia.
- The distraction callus consolidates 2 days for every day of distraction.
- A JawBra may be utilized to mold the mandible following distractor removal if an anterior open bite is present.

POSTOPERATIVE CARE

- The intubated child is transported to the NICU.
- After a 24-hour latency period, distraction proceeds at 1 mm of advancement performed twice daily for a total of 2 mm daily.
- The pin sites are gently cleaned and antibiotic ointment is applied twice daily.
- Extubation generally occurs between postoperative days 3 to 5.
- Weekly cephalograms and physical examination are utilized to monitor the progression of mandibular advancement, view the increase in posterior airway space, and confirm the proper position of the Steinmann pins.
- Distraction is complete when the mandible appears to have 5 mm of reverse overjet based on a lateral cephalogram (**FIG 2**).
- The distraction callus is consolidated 2 days for each day of distraction.

FIG 2 • Cephalograms are used to evaluate progression of the mandibular advancement, view the increase in posterior airway space, and confirm the placement of the Steinmann pins. The distraction is completed when the mandible appears to have 5 mm of reverse overjet based on a lateral cephalogram and physical exam.

- At the conclusion of the consolidation period, the external distractors and the Steinmann pins are removed under general anesthesia.

OUTCOMES

- Mandibular distraction osteogenesis (MDO) is safe and effective to treat obstructive sleep apnea (OSA) secondary to tongue-based airway obstruction from micrognathia.¹¹
- Compared to tracheostomy, the cost of treatment is markedly less due to the decreased need for airway procedures and home care costs.^{12,13}
- In general, prematurity, low birth weight, preoperative intubation, and syndromic diagnosis in addition to cardiac and pulmonary abnormalities, are not predictors for failure, defined as conversion to tracheostomy.¹⁴

COMPLICATIONS

- Infection is relatively uncommon due to the external placement of the distractors.
- Facial scarring is minimal unless pin traction occurs. This can be avoided with proper skin retraction during the initial placement of the Steinmann pins (**FIG 3A**).
- Improper pin and osteotomy placement can lead to tooth bud injury, pin migration through the bone, and injury to the inferior alveolar nerve (**FIG 3B,C**).
- Some relapse is anticipated due to the short consolidation period. This is compensated for with 5 mm of overdistraction.
- In our experience, anterior open bite has not been either a common short- or long-term finding. If encountered immediately following distractor removal, a JawBra is applied for mandibular molding.¹⁵
- We have not found TMJ ankylosis to be a common complication associated with this technique. By inserting the Steinmann pins anterior to condyles, loading is avoided through the distraction process.
- Failure of mandibular distraction with conversion to tracheostomy has been associated in neonates with a diagnosis of PRS without a cleft palate and those with gastroesophageal reflux and who required Nissen fundoplication.¹⁴

FIG 3 • **A.** Facial scarring is minimal unless pin traction occurs due to improper skin retraction during the initial placement of the Steinmann pins. Note the traction scarring from the mandibular pin. **B.** Note the placement of the pin beneath the tooth buds. **C.** Following removal of the pin, the tooth buds are spared.

CHAPTER Mandibular Setback

Haithem M. Elhadi Babiker and Deepak G. Krishnan

DEFINITION

- Surgical correction of maxillofacial skeletal deformities dates back to the late 19th century.
- Numerous techniques have been described for repositioning of the maxilla and mandible through various osteotomies.
- The bilateral sagittal split osteotomy (BSSO) is the most common surgical procedure for correction of mandibular deformities.
 - It was first described by Obwegeser in 1957.¹
 - The technique was modified by Dalpont in 1961² and further refined by Epker in 1977.³
- The BSSO setback is a procedure used for correction of mandibular prognathism and asymmetries through a series of connected osteotomies that posteriorly reposition the mandible.⁴

ANATOMY

- The mandible is a U-shaped bone forming the lower jaw. It is the only movable bone of the skull, articulating with the temporal bones at the temporomandibular joints.
- It consists of a horizontal horseshoe-shaped body and two broad and oblong rami projecting upward. The alveolar processes of the mandible house and support the mandibular teeth.
- The inferior alveolar nerve enters the mandibular foramen on the medial surface of the ramus near its center. It then extends downward and forward within the body of the mandible; it exits at the mental foramen, located on the external surface midway between the alveolar process and the lower border, in

the interval between the premolar teeth.

- The anteromedial margin of the mandibular foramen is guarded by an upward tonguelike projection, the lingula. Along its course, the inferior alveolar nerve innervates the mandibular teeth and terminates as the mental nerve, which supplies sensation to the skin and mucous membrane of the lower lip and chin.
- The muscles of mastication directly attach to the surface of the mandible. The masseter and medial pterygoid muscles attach to the lateral and medial surfaces of the ramus.
 - These two muscles form the pterygomassetric sling, which straddles the mandibular ramus.
- The lingual nerve, before reaching the tongue, comes in close contact with the inner surface of the alveolar border of the mandible in close proximity to the mandibular third molar.

PATHOGENESIS AND NATURAL HISTORY

- Mandibular prognathism is a condition in which the mandible is positioned anterior to the maxilla, referred to as class III malocclusion.
- In the NHANES study (1989–1994), 0.3% of the US population was reported to have mandibular prognathism severe enough to require orthodontic-surgical treatment.⁵
- About 14% of youth (less than 18 years of age) in the United States have a class III malocclusion. Roughly a quarter of these patients have isolated mandibular prognathism, whereas the remaining three-quarters have a combination of maxillary deficiency, in addition to mandibular protrusion.
- Mandibular prognathism causes aesthetic concerns, as well as chewing and speaking difficulties, prompting patients to seek surgical treatment at a younger age.
- In cases of severe mandibular prognathism, bimaxillary surgery is the preferred method of treatment (BSSO setback combined with maxillary advancement). This is because excessive mandibular setback may result in obstructive sleep apnea and is also subject to higher rates of relapse.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients usually present during the teenage years.
- The main complaints are difficulty with chewing and speech, and the aesthetic concerns of a large mandible. Often, the malocclusion also presents as an open bite.

- Patients are usually first seen by an orthodontist and eventually referred to a maxillofacial surgeon when ready for surgery.
- Orthodontic treatment is usually undertaken for approximately a year and serves to align the teeth within the dental arches and corrects any dental compensation.
- Surgery is undertaken when the patient reaches skeletal maturity and there is proof of growth cessation (girls 16–18 years, boys 18–20 years).
- Preoperative workup includes obtaining
 - Dental models
 - Cephalometric analysis
 - Face bow transfer to record the relationship of the jaws to the skull base
 - Model surgery to fabricate the surgical splints
- In the case of single-jaw surgery, a single splint is fabricated to help position the mandible.
- In the case of double-jaw surgery (LeFort I advancement combined with BSSO setback) for severe class III malocclusion, two splints are made: an intermediate splint used intraoperatively to position the maxilla in its final position and a final splint to position the mandible.
- If third molar teeth are present, they may be extracted 6 months prior to surgery.

IMAGING

- Lateral cephalometric radiographs are obtained for cephalometric analysis.
- Panoramic radiographs are obtained to determine the presence and location of mandibular third molar teeth and also level of the inferior alveolar canal.
- A CT scan with 3D images is obtained and can be used for virtual surgical planning (VSP) in lieu of traditional model surgery.

DIFFERENTIAL DIAGNOSIS

- Class III skeletal relationship can be secondary to mandibular prognathism, maxillary hypoplasia, or a combination of both.
- Accurate diagnosis is important to determine the appropriate surgery.
- The diagnosis is confirmed by detailed clinical evaluation combined with cephalometric analysis. Often, a midface deficiency is wrongly diagnosed as mandibular prognathism, whereas in reality upon cephalometric investigation, the mandibular position may be normal.
- Acromegaly and pituitary hyperactivity should be suspected in mandibular

prognathism that presents later in life, and appropriate workup should be undertaken.

- Unilateral hyperplasia of the mandible can cause an asymmetric prognathism and malocclusion. A neoplasm of the mandibular condyle should be ruled out in these cases. Unilateral condylar hyperplasia is an idiopathic rare condition that can also cause an asymmetric mandibular prognathism.

NONOPERATIVE MANAGEMENT

- Mild class III malocclusion can sometimes be treated with orthodontic management alone.
- True skeletal class III relationship can only be treated by surgical intervention.

SURGICAL MANAGEMENT

- The BSSO setback procedure is usually performed during the teenage years after skeletal maturity.
- The main objective of the operation is to correct mandibular prognathism by cutting the mandible and repositioning it posteriorly to meet the maxilla in a normal class I relationship.
- The main steps of the procedure are as follows:
 - Make bilateral intraoral incisions to expose the posterior aspect of the mandible.
 - Perform bilateral sagittal split osteotomies of the mandible (**FIG 1**).
 - Position the mandible into a class I relationship using an occlusal splint.
 - Use wires to perform maxillomandibular fixation.
 - Remove any bony interference between the two cut segments of the mandible.
 - Establish a proper position of the condyles in the fossae bilaterally.
 - Rigidly fixate the mandible in its new position.

FIG 1 • The BSSO procedure includes a medial ramus osteotomy, an anterior ramus horizontal osteotomy, and a vertical osteotomy.

Preoperative Planning

- The risks, benefits, and complications are discussed with the patient prior to surgery. Discussing the risk of damage to the inferior alveolar nerve is mandatory.
- The mandibular third molar teeth are preferably extracted 6 months prior to the surgery to allow adequate time for healing.
 - If they have not been extracted previously, they may be removed during the procedure.⁶
- The occlusal splints are tested on the patient preoperatively to ensure adequate fit.
- Preoperative photos are obtained for documentation.

Positioning

- The patient is positioned supine with the arms tucked in.

- They are intubated nasally, and the endotracheal tube is sutured to the nasal septum and secured appropriately to the forehead (**FIG 2**).

Approach

- Surgery is performed through an intraoral approach.

FIG 2 • The patient is positioned supine and the endotracheal tube is sutured to the nasal septum and then secured to the forehead.

TECHNIQUES

■ Exposure

- Clean the oral cavity with chlorhexidine or an equivalent antiseptic mouth rinse, and place a throat pack.
- Inject local anesthetic containing a vasoconstrictor to infiltrate the area of dissection.
- Insert a bite block on the opposite side to adequately open the mouth.
 - Place two Langenbeck retractors to pull away the cheek.
 - Place a tongue retractor to protect the tongue (**TECH FIG 1A**).
- Make a 3-cm incision along the external oblique ridge of the mandible from midway on the ramus to the level of the second molar tooth (**TECH FIG**

1B).

- If the mandibular third molar is present and indicated for removal, the incision is modified to incorporate the tooth.
- A sufficient cuff of gingiva (5 mm) is maintained adjacent to the molar teeth for a relaxed wound closure.
- Sharp dissection is extended through mucosa, muscle, and periosteum to raise a full-thickness mucoperiosteal flap, exposing the entire ascending ramus and posterior body of the mandible (**TECH FIG 1C**).
- Care is taken not to dissect the lateral muscular attachments along the anterior ramus ensuring adequate blood supply to the proximal segment of the mandible.
- Expose the inferior border of the mandible in the area of the planned vertical osteotomy.
 - Keep the periosteum intact to prevent excessive bleeding and herniation of the buccal fat.
 - Strip enough of the masseter muscle to adequately visualize the planned vertical osteotomy site (**TECH FIG 1D**). Keep as much of the masseter as possible attached to the proximal segment of bone to prevent bony devascularization. At the anterior extent of the incision, the depressor anguli oris attaches tenuously to the inferior border of the mandible. This area must be stripped off sternly to adequately mobilize the mandible after the osteotomy.
- Place a notched ramus retractor over the anterior border of the ramus and strip the lower fibers of the temporalis muscle from the coronoid process. A curved Kocher clamp is then inserted to retract tissue and expose the entire border of the ascending ramus (**TECH FIG 1E**).
- Dissect the periosteum from the internal oblique ridge to the medial side of the retromolar area (**TECH FIG 1F**). Then extend the dissection inferiorly to the region of the lingula and mandibular canal.
 - A malleable retractor is inserted on the medial aspect of the ramus to retract and protect the neurovascular bundle (**TECH FIG 1G**).

A

B

C

D

TECH FIG 1 • A. Exposure is obtained by Langenbeck retractors to pull away the cheek and a tongue retractor to protect the tongue. **B.** An incision is made along the external oblique ridge halfway up the ramus to the level of the second molar tooth. Leave enough gingival cuff to facilitate easy closure. **C.** Sharp dissection is undertaken to raise a full-thickness mucoperiosteal flap to expose the ramus and posterior body. **D.** Using a sharp elevator, the masseter muscle fibers are stripped to expose the planned vertical osteotomy site. **E.** A curved Kocher clamp is used to retract tissue over the ascending ramus. **F.** The periosteum is dissected from the internal oblique ridge to expose the medial ramus. **G.** A malleable retractor is used to protect the neurovascular bundle.

■ Osteotomy of the Medial Ramus

- The medial ramus osteotomy is performed first. This is a horizontal osteotomy through the medial cortex of the ramus.
- A short, straight-blade reciprocating saw or a Lindemann bur is used to make the osteotomy (**TECH FIG 2A**).
- The osteotomy should not extend more than 2 cm posteriorly (Hunsuck modification) and should be low and parallel to the occlusal plane (**TECH FIG 2B**).
- By keeping the medial osteotomy short and low (**TECH FIG 2C**); the incidence of a “bad split” is reduced.
- Ensure that the osteotomy extends to the medullary bone (**TECH FIG 2D**).
- The osteotomy is then directed anteriorly, remaining inside the buccal cortex, into medullary bone, and ends inferiorly, immediately lateral to the second molar tooth (**TECH FIG 2E**).
 - The presence of an impacted wisdom tooth may make the osteotomy difficult. In this case, the osteotomy is carried through the tooth as if it were bone.
 - Avoid excessive angulation of the saw blade, keeping it parallel to the osteotomy, so as not to weaken the buccal cortex and cause a fracture.

TECH FIG 2 • **A.** The medial osteotomy is made with a reciprocating saw blade. **B.** Hunsuck modification. The medial osteotomy should not extend more than 2 cm posteriorly to avoid a bad split. Horizontal osteotomy parallel to the occlusal plane (see arrow). **C.** The medial osteotomy is short, low, and parallel to the occlusal plane of the mandibular teeth. **D.** Ensure that the osteotomy is into bleeding medullary bone. **E.** The medial osteotomy is continued onto the anterior ramus and ends at the level of the second molar.

■ Mandibular Osteotomy and Split

- The vertical osteotomy of the mandibular body is then made.
 - Remove the bite block and the curved Kocher clamp to relax the soft tissue

and improve access to the inferior border of the mandible.

- Place a Channel retractor at the inferior border of the mandible and rotate it into position to improve visibility of the planned osteotomy site.
- The assistant may pull on the mandible and rotate it in the opposite direction to enhance access (**TECH FIG 3A**).
- The osteotomy location will depend on the planned buccal extension of the proximal segment (Dalpont modification).
- A fissure bur is used to make the vertical osteotomy (**TECH FIG 3B**).
 - Start the osteotomy at the inferior border and angle it superiorly to join the anterior osteotomy that was previously completed (**TECH FIG 3C**).
 - Ensure that the bur penetrates the cortex into bleeding medullary bone. Take extra care not to injure the neurovascular bundle, which tends to be situated very close to the buccal cortex in cases of mandibular prognathism (**TECH FIG 3D**).
 - Adequately cut the entire inferior border of the mandible and include it in the osteotomy.
- After the vertical osteotomy is completed, retractors and bite block are reinserted in preparation for completion of the mandibular split.
- A thin 10-mm rigid osteotome is used with a mallet to tap along the entire length of the osteotomy to confirm completeness of the cortical cuts (**TECH FIG 3E**).
 - Twisting of the osteotome should produce movement between the segments including the inferior border (**TECH FIG 3F**).
- To split the mandible, a large, 10-mm osteotome is placed into the osteotomy near the second molar tooth and a smith (sagittal split spreader) forceps is placed near the inferior border.
 - By simultaneous twisting and spreading, the two segments are slowly split under direct vision (**TECH FIG 3G**).
 - If the split does not start spontaneously, stop and redefine all osteotomies.
- As the split starts, be certain that the neurovascular bundle is visualized and remains with the distal segment (**TECH FIG 3H**).
 - If the neurovascular bundle is still attached to the proximal segment, use blunt forceps to gently tease it free (**TECH FIG 3I**).
 - If the split results in transection of the inferior alveolar nerve, microneurosurgical repair is performed prior to proceeding further.
- Ensure that the inferior border splits with the proximal segment (**TECH FIG**

3J), so as to avoid a “bad split.”

- The mandible should be well supported during the splitting process to avoid damage to the temporomandibular joint.
- A curved Kocher clamp is applied to the distal part of the proximal segment and used as a handle to apply force in all directions to ensure complete separation of the two segments.
- The same steps are repeated on the contralateral side with sagittal splitting of the ramus.

TECH FIG 3 • **A.** The bite block is removed and the assistant pulls the mandible laterally, away from the operator, to enhance access to make the vertical osteotomy. **B.** A bur is used to make the vertical osteotomy. **C.** Bur completing the vertical osteotomy and joining it with the anterior ramus osteotomy. **D.** Avoid injuring the neurovascular bundle when making the vertical cut. **E.** Use a rigid osteotome to complete the cuts. **F.** Before completing the split, twist the osteotome inside the osteotomy. Some separation of the segments should be seen indicating that the cuts are complete. **G.** Simultaneous twisting and spreading to complete the split. **H.** Split completed. Notice how the nerve is not visualized within the proximal segment and remains with the distal segment. **I.**

Neurovascular bundle being teased free from the proximal segment. **J.** Inferior border completely cut and remains with the proximal segment.

■ Occlusal Correction and Maxillomandibular Fixation

- If there are impacted mandibular third molars, they are removed at this point using dental elevators.
 - The wisdom tooth will be located within the distal segment and is usually cut while performing the anterior osteotomy.
 - Avoid fracturing the lingual cortex of the distal segment while removing the tooth.
- Using a sharp periosteal elevator, strip any remaining pterygomassetric sling at the inferior border of the distal segment.
 - This allows free movement of the distal segment and facilitate placement onto the occlusal splint.
- Similarly, strip the attachment of the medial pterygoid muscle from the medial aspect of the proximal segment.
 - This maneuver prevents interference when positioning the distal segment posteriorly and allows for proper seating of the condyle in the glenoid fossa.
- Use a large bur to smooth the contact areas between the two bony segments; this will ensure proper apposition and rigid fixation.
- Mobilize the distal segment with digital pressure to ensure that the two segments move freely.
- Using 26-gauge wire loops, wire the two jaws together into occlusion using the prefabricated occlusal splint (**TECH FIG 4**).

TECH FIG 4 • Occlusal splint used as a guide for maxillomandibular fixation.

■ Removal of Bony Interference

- Setting the mandible posteriorly will result in overlap between the proximal and distal segments.
 - This amount of overlap has to be removed for proper apposition between the two segments in preparation for rigid fixation.
- Position the proximal segment with a hemostat or wire positioner with the condyles properly seated.
- Mark the proximal segment for the amount of bony overlap that needs to be removed (**TECH FIG 5A**).
- The bony overlap should coincide with the planned setback (plus the width of the osteotomy cut). Protect the neurovascular bundle during removal the bony overlap with a saw or rongeur (**TECH FIG 5B**).
- Remove enough bone to facilitate optimal bone contact between the distal and proximal segments.
- Check the lingual plate of the distal segment to determine the need for removal of further bony interferences.

TECH FIG 5 • A. Marking the proximal segment for the amount of bony overlap indicated for removal. **B.** Bony overlap removed with a saw.

■ Condylar Positioning and Rigid Fixation

- Using a wire instrument or a fine curved hemostat applied to the most distal edge of the proximal segment, digital pressure is applied extraorally at the angle of the mandible to seat the condyle in the glenoid fossa.
 - Enough pressure is applied to seat the condyle into its preoperative centric relation (**TECH FIG 6A**).
 - The inferior borders of the proximal and distal segments are lined up so that there is no palpable step in the final position.
- A bone clamp is used to hold the two segments together in that position in preparation for rigid fixation.
- Rigid fixation is achieved by three or four bicortical screws placed transcutaneously.
- A lateral neck stab incision is made just below the inferior border of the mandible at the level of the gonial notch.
 - A hemostat is then used to bluntly dissect through the stab incision.
 - The trocar is introduced through the neck incision to gain access intraorally.
 - Use two fingers intraorally to guide the trocar to pierce the periosteum and reach the bone (**TECH FIG 6B–E**).
- Remove the pin and place the cheek retractor to improve visualization.

- The drill is introduced through the trocar and used to drill through both proximal and distal segments (**TECH FIG 6F**).
- The screw location is determined by areas of best bony contact, away from the neurovascular bundle.
- Screws should be placed as far apart as possible to improve stability.
- They are placed either in a straight line across the superior border or in a triangular fashion with one screw placed at the inferior border (**TECH FIG 6G**).
- After each hole is drilled, the trocar is maintained in position, the hole is measured, and the screw is placed accurately through the trocar and gently tightened (**TECH FIG 6H**).
- While tightening the screw, ensure that the screw is engaging the distal segment. If the two segments are able to be pushed apart, the screw should be removed and a new hole drilled.
- Ensure that the screws do not compress the bone segments, which may result in displacement of the condyle resulting in relapse (**TECH FIG 6I**).
- The same steps are repeated on the contralateral side to fixate the bony segments.
- An alternative to screws is to use a plate with monocortical screws to secure the two segments together.

TECH FIG 6 • A. A wire instrument is used to seat the condyle while simultaneously applying external digital pressure. The bone clamp is then tightened to hold

the two segments together in preparation for rigid fixation. **B.** Stab incision in the neck at the level of the gonial notch. **C.** Blunt dissection using a hemostat through the stab incision. **D.** The trocar is inserted through the incision. **E.** Trocar gaining access intraorally using two fingers as a guide. **F.** Drill introduced through the trocar. **G.** Screw configuration. **H.** Keep the trocar absolutely still after drilling the hole and then place the screw. **I.** Positional screws are placed to engage both segments without displacing the condyle from the glenoid fossa.

■ Completion

- Remove maxillomandibular fixation and determine the occlusion.
 - The mandible is opened and closed multiple times to check that the occlusion is symmetric, stable, and reproducible, as planned.
 - If the occlusion is not correct, do not be tempted to “manipulate” the mandible into occlusion with elastics or wires. Rather, remove the fixation and repeat the fixation steps as above, ensuring that the condyles are passively seated within the glenoid fossa.
 - The wounds are then thoroughly irrigated and closed with continuous, watertight 3-0 chromic.
 - The skin stab incisions are approximated with 5-0 nylon sutures.
 - The mouth is irrigated and suctioned and the throat pack is removed.
 - Place interdental elastics to secure the occlusion. The elastics are placed in a class III fashion to reinforce the setback movement.
-

PEARLS AND PITFALLS

Physical findings

- Class III skeletal relationship can be due to mandibular prognathism, maxillary hypoplasia, or a combination of both. Accurate diagnosis is critical to determine the appropriate surgery to correct the deformity.

- Mandibular setbacks in general reduce airway space at the level of the base of tongue. This can create obstructive sleep apnea.

Technique

- Leaving an insufficient cuff of gingiva when making the incision will lead to difficulty suturing and possible wound dehiscence.
- Improper handling of the tissue during dissection may lead to perforation of the periosteum, herniation of buccal fat, hemorrhage, and excessive postoperative swelling.
- Making the medial ramus osteotomy too far posteriorly may lead to a bad split. Keep the medial osteotomy short and low, closer to the occlusal plane of the mandibular teeth.
- Ensure that all the osteotomies are deep enough into bleeding medullary bone.
- The anterior ramus osteotomy should be precise to avoid weakening of the buccal cortex resulting in fracture of the proximal segment.
- When making the vertical osteotomy, be certain to completely cut the inferior border of the mandible to avoid a bad split.
- Be careful not to cut too deep in the area of the neurovascular bundle.
- When performing the split, the two segments should separate easily; the inferior border of the mandible splits and stays with the proximal segment. If the mandible is not splitting with ease, stop and redefine the osteotomies.
- If a bad split occurs, complete the splitting process as planned, and fixate the fractured fragments similar to a mandible fracture.
- Ensure that all bony interferences have been removed.
- Choose the location of the skin stab incisions carefully to avoid struggles with screw fixation. This step can be very frustrating if the trocar is not kept absolutely still after drilling the holes. Redrilling the holes multiple times may weaken the bone and jeopardize the fixation.
- Appropriate positioning of the condyle is the most critical step of the procedure.
- Immediately after removal of the maxillomandibular fixation, the occlusion should be exactly as planned. Do not accept an incorrect occlusion. There is no better time to correct this problem than at this stage, in the operating room.

POSTOPERATIVE CARE

- The patient is generally extubated in the operating room and taken to the recovery room breathing spontaneously. If there are any airway concerns, the patient may be taken to the ICU while still intubated.

- If any airway need arises, the interarch elastics may be removed and replaced later when the patient is stable.
- The patient is maintained on a soft diet for 6 weeks.
- The elastics and splint are removed in 2 weeks and guiding elastics placed.

OUTCOMES

- Relapse after the BSSO setback depends on the magnitude of the setback, especially in growing individuals. Relapse rates reported in the literature vary widely, with a range of 7% to 50%.
- Cessation of lower jaw growth in individuals with true mandibular excess may occur later than it does in individuals with normal occlusion. For this reason, surgery is best delayed until confirmation of growth cessation (comparison of lateral cephalograms obtained 6 months apart).

COMPLICATIONS

- An unfavorable bad split is not an uncommon complication, with an incidence of up to 23%.
 - A bad split could be a fracture of the buccal/lingual plate, or a more serious situation in which the condyle remains with the distal segment.
 - If this occurs, an additional osteotomy is required to free the condyle (**FIG 3**).
 - Occurrence of a bad split should be recognized intraoperatively and additional rigid fixation may be needed.
- Injury to the inferior alveolar nerve may occur while making the osteotomies or while placing the screws. The reported incidence varies greatly in the literature, but patients seem to adapt well to the sensory deficit in the long term.
- Lingual nerve injury is a rare complication. It occurs during the subperiosteal dissection along the medial ramus, or during bicortical screw fixation. Avoid using very long screws (more than 15 mm) that extend beyond the lingual cortex.
- Injury to the facial nerve can occur but is a very rare complication.

FIG 3 • A bad split can occur with fracture of the buccal cortex or higher near the condyle, resulting in a third segment.

- Significant bleeding is rarely encountered. Potential sources are the facial artery and the retromandibular vein. It is prevented by careful surgical technique and protection of the soft tissue.
- Wound dehiscence and/or infection are rare complications and are most often related to poor oral hygiene.

CHAPTER Osseous Genioplasty

Mark E. Walker and Derek M. Steinbacher

DEFINITION

- Osseous genioplasty is an operative technique wherein the surgeon performs an osteotomy proximal to the mental prominence allowing for the repositioning of the chin to improve facial harmony.
- Mobilizing this segment enables the surgeon to address the complete spectrum of chin deformities including asymmetry, as well as vertical and sagittal deficiency, and excess.
- Size, shape, and position of the chin can enhance or detract from normal facial harmony and symmetry.
- Chin appearance influences social perceptions of masculinity and femininity.

ANATOMY

- Anterior labial vestibule of the lower lip is the outermost layer forming the labiogingival sulcus.
- Deep to the labiogingival mucosa, the two bellies and median raphe of the mentalis muscle insert onto and cover the chin.
- Mentalis muscle is the sole elevator of the lower lip and chin providing major vertical support.
- Mental nerve courses inferiorly (4.5 ± 1.9 mm) and anteriorly (5.0 ± 1.8 mm) within the canal prior to exiting at the mental foramen (**FIG 1**).

FIG 1 • Mental nerve courses inferiorly (4.5 ± 1.9 mm) and anteriorly (5.0 ± 1.8 mm) within the canal prior to exiting at the mental foramen.

- Osteotomy is designed inferior to this path to avoid damage to the mental nerve.
- Submental posterior insertion of the genioglossus muscle is responsible for blood supply to the bone flap following osteotomy.

PATHOGENESIS

- Chin asymmetry and/or malposition can be congenital or traumatic in etiology.
- Malocclusion and maxillomandibular discrepancy can contribute to chin malposition.

NATURAL HISTORY

- In the setting of an open bite, progressive worsening of retrognathia, often perceived as microgenia, should be investigated for possible temporomandibular joint resorptive processes, such as idiopathic condylar

resorption.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Inquire about any history of dentofacial trauma or prior maxillofacial surgery.
- Assess patient for maxillomandibular discrepancy or obvious dentofacial abnormalities.
- Simple visual inspection of the vertical and sagittal position can identify microgenia, macrogenia, and chin asymmetry.
 - Microgenia, or small chin, is defined as some combination of vertical and sagittal deficiency (**FIG 2A**).
 - Macrogenia, or large chin, is defined as some combination of vertical and sagittal excess (**FIG 2B**).
 - Asymmetry assessed on frontal view can present with vertical and/or rotational components (**FIG 2C**).
- Ideal chin projection is described in relation to the lips, nose, and midface.
- Cephalometrics is a powerful tool to generate objective descriptors of chin position.
 - Distance between soft tissue nasion to soft tissue chin (2 mm)
 - Depth of the labiomental fold (4 mm)
 - Cervicomental angle (acute vs obtuse)
 - Ricketts S-line
 - Line that connects the soft tissue nasion with the menton, the distance from which measures 2 mm at the upper lip prominence and 4 mm at the lower lip prominence¹ (**FIG 3A**).
 - Riedel plane
 - Line that connects but does not cross the most prominent portion of the upper and lower lips and connects with the soft tissue menton² (**FIG 3B**).

FIG 2 • **A.** Vertical and sagittal microgenia. **B.** Vertical and sagittal macrogenia. **C.** Frontal asymmetry secondary to unilateral vertical microgenia and rotation.

■ Facial convexity angle

- On lateral view, this is the angle defined by the pogonion position in relation

to a vertical line connecting the glabella and subnasale¹ (**FIG 3C**).

IMAGING

- Panorex to assess dentition and mandibular growth
- Cone-beam CT (CBCT) can be used for 3D assessment and surgical planning/modeling.
- Three-dimensional digital photography can be used to evaluate chin volume, position, and symmetry.
 - Simulation function can also be used for preoperative discussion/planning.
- Assess position of mental foramen, canal pattern, and tooth root apices.

DIFFERENTIAL DIAGNOSIS

- Isolated microgenia
- Isolated macrogenia
- Overall micrognathia or retrognathia
- Chin asymmetry
- Some combination of the above
- Craniofacial conditions or syndromes may be the underlying etiology.

NONOPERATIVE MANAGEMENT

- There are no conservative treatment measures available for correcting chin position.
- Patients do have the option for no intervention should they not wish to pursue surgery.

FIG 3 • A. Ricketts S-line. B. Reidel plane. C. Facial convexity angle.

SURGICAL MANAGEMENT

- Operative interventions to address chin aesthetics include the implantation of alloplastic materials (ie, porous polyethylene or silicone implants) and surgical osseous genioplasty.
- Indications for surgical intervention include displeasure with one's appearance, with the patient specifically identifying the chin as an area of focus.
- The balance between lip, nose, and midface position must be addressed with the patient, as any deformity or asymmetry in these areas may either be contributing to the appearance of chin disharmony or may become more obvious after the chin has been addressed.
- The risks of osseous genioplasty include bleeding, infection, injury to the mental nerve, paresthesias, injury to the mentalis muscle, “witch chin” deformity, mentalis muscle, pain, poor wound healing, scarring, persistent asymmetry, hardware malfunction, and the need for future additional operations.
- Each skeletal configuration on the differential diagnosis list calls for a unique surgical solution to address the problem or some combination of these.
- The surgical steps for correction vary primarily in the planning and execution

of the osteotomies and positioning and fixation of the bony segment:

- Microgenia, vertical—lengthen (vertically)
- Macrogenia, sagittal—setback (usually wedge removed)
- Macrogenia, vertical—shorten (wedge removed)
- Asymmetry, frontal—rotate (mediolateral)
- Asymmetry, vertical—wedge reduction
- Combination—combination of the above

Preoperative Planning

- Panorex and CBCT imaging should be reviewed prior to any surgical procedure to assess for dental maturity and cessation of bone growth.
- Based on clinical and skeletal analysis, the osteotomy is planned to address each patient on a case-by-case basis.
- The surgeon must explain to the patient that this is a primarily cosmetic procedure and expectations should be set early that this may include out-of-pocket expenses, even if combined with other insurance-covered surgery.

Positioning

- The patient is placed supine on the operating table with the head positioned in a semi-extending position on the head rest.
- Nasal RAE endotracheal tube is used for intubation with exception of concurrent rhinoplasty.
- The entire face, mouth, ears, and neck should be prepped with Betadine or chlorhexidine solution while protecting the corneas. Steri-Strips are placed to secure the eyelids.
- A head drape is placed securing the patient's hair and clearing the operative field.
- The surgeon must visualize the entire face given the chin's role in facial harmony.
- A throat pack is placed into the oral pharynx to minimize ingestion of irrigation solution and blood throughout the procedure.
- Local anesthetic with epinephrine is injected for regional anesthetic and hemostatic effect prior to incision.
- Decadron is administered preoperatively to control postoperative edema.
- Perioperative antibiotics are administered to prevent surgical site infections (ie, cefazolin or clindamycin).

TECHNIQUES

■ Basic Surgical Steps

Exposure

- The anterior labial vestibule is incised using a no. 15 blade scalpel perpendicular to the mucosa with a dart designed at the lower lip frenulum³ (**TECH FIG 1A**).
- This incision is placed at least 10 mm from the mucogingival line.
- Using a fine tip Colorado blade electrocautery, a horizontal incision is made through the mentalis muscle, preserving a cuff at the gingival border, allowing precise reattachment at closure (**TECH FIG 1B**).
- Blunt dissection is then performed with an elevator to expose and visualize the mental nerves as well as the mental prominence and associated structures.

Osteotomy Design

- Midline should be marked prior to osteotomy design.
- The osteotomy is then traced with a sterile pencil above the pogonion, avoiding the mental nerves but typically extending laterally beyond the mental foramina (**TECH FIG 2A**).

TECH FIG 1 • **A.** The anterior labial vestibule is incised using a no. 15 blade scalpel perpendicular to the mucosa with a dart designed at the lower lip frenulum. **B.** Cuff of mentalis muscle remains attached

to mandible (*arrow*) to facilitate closure. Mental nerve (*).

TECH FIG 2 • A. The osteotomy extends lateral to the mental foramen (*arrow*). Mental nerve (*). **B.** Genioglossus muscle remains attached to the mobile bony segment (*arrow*). **C.** Inferior osteotomy (*arrow*) is performed first in shortening genioplasty with planned wedge resection. In cases of prominent tubercles (**D**), a pineapple bur or reciprocating rasp is used to smooth the contour (**E**).

- Angulation and wedge resection might be planned based on anticipated course.
- Using the reciprocating saw, the planned osteotomies are performed. Irrigate the blade with saline to prevent thermal injury to the mandible and surrounding structures.
- Leave the genioglossus muscle attached to retain blood supply to the mobile segment(s) (**TECH FIG 2B**).
- In the case of a shortening genioplasty, where wedge resection is planned, the inferior osteotomy is performed first (**TECH FIG 2C**).
- In cases of asymmetry, wedge resection will be unilateral.
- For cases with prominent tubercles, the pineapple bur or reciprocating rasp is

employed to smooth the contour (**TECH FIG 2D,E**).

Fixation

- The mobile genioplasty segment is secured to the mandible using a variety of surgical plates and screws depending on the goals of the procedure.
- Options include the X-plate, step-off advancement plate, and straight H-plate (**TECH FIG 3A–E**).

TECH FIG 3 • Fixation can be accomplished with a variety of plates, including the X-plate (**A**), the step-off advancement plate (**B**), and the straight H-plate (**C**).

Closure and Dressing

- Following bony fixation, the oral cavity and surgical field are irrigated with Betadine and normal saline solution.
- Precise reattachment of the mentalis muscle over the plate/screws is critical for good outcomes, both functionally (lower lip motion) and aesthetically (soft tissue volume/contour).
- Multiple interrupted 3-0 Vicryl sutures are used to reapproximate the muscle (**TECH FIG 4A**).
- The overlying mucosa is then reapproximated with 3-0 chromic gut sutures.
- A chin dressing is applied using Mastisol, surgical tape (elastoplasty tape is used by the authors), and Tegaderm designed to provide additional support and limit edema to the chin postoperatively (**TECH FIG 4B**).
- The patient is placed in a face bra once the dressing has been applied to provide additional external support to the mandible and soft tissues of the chin (**TECH FIG 4C**).
- This dressing is removed at the time of follow-up, approximately 1 week

after surgery.

TECH FIG 4 • A. Using 3-0 Vicryl suture, the mentalis muscle (*arrow*) is closed over the underlying hardware and precisely repositioned to avoid chin deformity. **B.** A chin dressing is applied using Mastisol, surgical tape (elastoplasty tape is used by the authors), and Tegaderm designed to provide additional support and limit edema to the chin postoperatively. **C.** The patient is placed in a face bra once the dressing has been applied to provide additional external support to the mandible and soft tissues of the chin.

■ Variations

Osseous Genioplasty for Sagittal or Vertical Microgenia

■ Advancement and vertical lengthening (**TECH FIG 5**)

Osseous Genioplasty for Sagittal Macrogenia

- Setback, typically with wedge resection (**TECH FIG 6A–D**)

Osseous Genioplasty for Vertical Macrogenia

- Shortening, typically with wedge resection (**TECH FIG 7A,B**)

Osseous Genioplasty for Frontal or Vertical Asymmetry

- Rotation (medial or lateral), typically with wedge resection and reduction (**TECH FIG 8A–D**)

TECH FIG 5 • A,B. In cases of both vertical and sagittal microgenia, a combination of advancement and vertical lengthening will be required to achieve the desired aesthetic result.

TECH FIG 6 • A,B. Preoperative planning for setback genioplasty in a patient with sagittal and vertical macrogenia. **C,D.** Setback genioplasty with wedge resection for a patient with sagittal macrogenia.

TECH FIG 7 • A,B. The osseous genioplasty for vertical macrogenia typically involves a wedge

resection and impaction of the bony segment, reducing the vertical height of the chin.

TECH FIG 8 • A–D. In cases of combined vertical and frontal asymmetry, a combination of wedge resection and unidirectional rotation may be required to achieve the desired result.

PEARLS AND PITFALLS

Preparation

- When draping, it is essential to visualize the entire face and upper neck given the chin's role in facial harmony.

Intraoperative edema management

- The use of preoperative Decadron can reduce postoperative edema and lead to faster patient recovery and satisfaction.

Incision

- Place the incision so that a cuff of muscle at the gingival border

planning	remains attached to the mandible to facilitate ease and precision of closure at the end of the case and minimize postoperative dehiscence.
Nerve preservation	■ Do not avulse the mental nerves when mobilizing the bony segment.
Blood supply	■ The genioglossus muscle should remain attached to the bony segment because this is the primary blood supply to the bone flap.
Closure	■ It is critical to precisely reattach the mentalis muscle at the time of closure to preserve functionality (lower lip motion) and aesthetics (soft tissue volume/contour) and prevent chin ptosis, or witch's chin deformity.

POSTOPERATIVE CARE

- Head elevation and ice pack application are encouraged to minimize edema.
- Patients are instructed to use warm salt water rinses and Peridex rinses postoperatively to manage oral flora.
- A short course of clindamycin or amoxicillin is prescribed postoperatively to reduce infection risk.
- Patients are instructed to avoid sports, physical exercise, or activities that might induce facial trauma for at least 6 weeks.
- Dental soft diet is recommended for the first 1 to 2 weeks after surgery.
- Pain control can be achieved with a combination of over-the-counter anti-inflammatory medications (ie, ibuprofen and acetaminophen) and narcotics (ie, hydrocodone or codeine prescriptions).
- Patients are instructed to follow up in the clinic 1 week after surgery for dressing removal and 3D photographic imaging (ie, Vectra camera).

OUTCOMES

- Functional and aesthetic outcomes are excellent in thoughtfully planned and well-executed procedures using osseous genioplasty to correct mild to moderate sagittal chin deficiencies.
- Osseous genioplasty provides the advantage of 3D versatility, larger advancements, and decreased foreign body-related complications when compared to alloplastic implants (ie, silicone, porous polyethylene).
- Only osseous genioplasty addresses both vertical excess and anterior mandibular asymmetry.

COMPLICATIONS

- Mental nerve sensory deficits following this dissection have been reported in the literature ranging from 6% to 10%.⁴⁻⁷

FIG 4 • Chin ptosis, or witch's chin deformity, may result if the mentalis muscle is not precisely reapproximated at the time of closure resulting in a senile appearance.

- Chin ptosis, or “witch’s chin” deformity, can result with failure to precisely reapproximate the mentalis muscle after dissection⁸ (**FIG 4**).

45 Alloplastic Chin Augmentation

CHAPTER

Barry L. Eppley and Sunil Tholpady

DEFINITION

- Alloplastic chin augmentation involves a three-dimensional shape change using implants.
- The most common alloplastic chin augmentation used is with a silicone material.¹

ANATOMY

- The chin is the anterior extension of the mandible, which has a dominant influence on the shape of the lower face and the neck below it.
- The shape of the chin is a function of the thickness of the bone and how well the ramus and body of the mandible have developed.
- Class II and III malocclusions are always associated with obvious aesthetic chin deformities.
- The classic ideal chin position aligns with a vertical line dropped from the base of the nose and the forward position of the lips.
 - A male chin should fall close to this line, whereas an aesthetic female chin can be positioned behind this line (**FIG 1**).

PATHOGENESIS

- Chin hypoplasia should be viewed as a three-dimensional problem that involves
 - Horizontal chin projection
 - Vertical chin height
 - Transverse chin width

NATURAL HISTORY

- Once complete mandibular growth has occurred by the late teens or early 20s, no further change in the chin shape or forward projection will occur.

FIG 1 • Aesthetic chin projection assessment in a woman **(A)** and a man **(B)**.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Occlusion (class I or II)
- Amount of horizontal chin weakness
- Vertical chin height
- Depth of labiomental fold
- Desired position of chin determined with the help of computer imaging
- Presence of chin dimples or vertical chin cleft

IMAGING

- Standard imaging includes patient photographs from multiple views (front, side, and oblique).
- Cephalometric x-rays and pantomogram can be used to evaluate hard tissue position and mental nerve foramen location.
- Three-dimensional (3D) computed tomography (CT) is useful if a custom chin implant is needed or prior chin implant or bony genioplasty has been performed.

DIFFERENTIAL DIAGNOSIS

- Isolated chin deficiency vs total mandibular deficiency

NONOPERATIVE MANAGEMENT

- Synthetic injectable fillers
- Fat injections

SURGICAL MANAGEMENT

- Aesthetic chin augmentation can be performed at any age beyond the early teenage years. Absolute skeletal maturity does not have to exist in severe chin deficiencies.
- There are no absolute contraindications other than the patient's willingness to accept a synthetic facial implant.
- Determine what style and size of chin implant are needed based on aesthetic objectives (**FIG 2**).

Preoperative Planning

- Computer imaging of facial photographs should be completed before surgery to determine the exact goals and expectations of the chin augmentation surgery.

Positioning

- The patient is placed in the supine position on the operative table.
- The procedure can be performed with local anesthesia, IV sedation, or general anesthesia, depending upon patient and surgeon preference.
- Regardless of anesthetic choice, local anesthetic of 2% Xylocaine with 1:100,000 Epinephrine is infiltrated into the proposed incision and the region of the chin.
- Mental nerve blocks can be performed first if the procedure is done under local anesthesia.

FIG 2 • Clinical examples of different chin implant styles.

TECHNIQUES

■ Exposure and Pocket Creation

- A submental incision employs a 3-cm incision within or directly behind the submental skin crease (**TECH FIG 1**).
 - When using larger or custom chin implants, the incision may be placed further behind the submental skin crease to compensate for significant forward positioning of the soft tissue chin pad.
 - Dissection proceeds through the mentalis muscle to reach the inferior portion of the bony chin.
- An intraoral incision uses a 3-cm mucosal incision above the depth of the vestibule on the lower lip side (**TECH FIG 2**).

- Dissection proceeds through the superior attachment of the mentalis muscle by leaving a cuff of muscle attached to the bone to aid closure.^{1,2}
- Subperiosteal dissection is performed over the entire chin bone, extending laterally below the mental nerve foramen if the chin implant has extended wings (such as an anatomic chin implant) (**TECH FIG 2B**).
- The dissection should extend inferiorly to the mandibular border and superiorly to accommodate the exact height of the implant.

TECH FIG 1 • **A.** Submental approach to chin augmentation. **B.** Retraction of soft tissue gives good exposure of the bony chin.

TECH FIG 2 • **A,B.** Intraoral approach to chin augmentation.

■ Implant Placement and Fixation

- The chin implant is placed into the pocket with the sides of the implant extended into the lateral dissection along the inferior border of the mandible.
 - The midline marker on the implant helps achieve a centric position on the bone.
 - Careful implant positioning includes checking for tilt, as this will lead to exaggerated asymmetry at the lateral wings.
 - Fixation of a chin implant is not always necessary but is highly desired.
 - In a submental approach, fixation can be achieved with sutures or small titanium screws (1.5 or 2.0 mm) along the inferior border.
 - In an intraoral approach, the only secure method to maintain the implant low on the bone is screw fixation.
 - Closure over the implant should be performed in three layers: muscle, dermis, and epidermal skin closure.
 - With intraoral approaches, resuspension of the mentalis muscle up and over the implant is critical.
-

PEARLS AND PITFALLS

Presurgical assessment with computer imaging

- Evaluate each patient for potential chin augmentation changes from three picture views.

Chin implant selection

- Chin implants change the projection of the lower face in three dimensions, not just from a profile view.

Subperiosteal implant placement

- There is no biological advantage to place the implant above the periosteum.

Implant positioning

- The implant needs to slide back and forth freely in the pocket to ensure that the lateral wings are not bent or folded.

Intraoral approach

- Screw fixation is essential to prevent immediate upward migration of the implant.

Postoperative management

- Patients need to wait 6 to 12 wk after surgery for an

accurate assessment of the implant results.

POSTOPERATIVE CARE

- A chin strap or tape may be used for a few days for postoperative compression.
- Intraoperative IV steroids can be used to help decrease swelling.
- Intraoperative IV and postoperative oral antibiotics with coverage of staphylococcal and oral flora are preferred for 5 to 7 days after surgery.

OUTCOMES

- Implants always increase chin projection.
- The style and shape of the implant, as well as the patient's expectations, will determine whether the aesthetic objectives are achieved.

COMPLICATIONS

- Infection usually presents as new swelling and pain 2 to 3 weeks after surgery.
- Asymmetry can be assessed no sooner than 6 weeks after surgery when most of the swelling has resolved in order to determine the midline positioning of the implant and/or wing asymmetry.
- Nerve impingement. Unremitting pain and numbness on one side that have been present for up to a month after surgery may indicate mental nerve compression by the wing of the implant.
- Overcorrection/undercorrection. The surgeon should allow a full 3 months after surgery for all swelling to subside and for the patient to adjust to his/her new look. Earlier interpretation, particularly that of overcorrection, may be premature.

46 Surgical Removal of Fibrous Dysplasia From the Craniofacial Skeleton

CHAPTER

Alexander Govshievich and Gaby G. Doumit

DEFINITION

- Fibrous dysplasia (FD) is a benign bone disorder characterized by progressive replacement of normal bone by abnormal fibrous tissue.
- FD accounts for 2.5% of all bony tumors and 5% to 7% of all benign bony tumors.¹
- This disorder may be monostotic (MFD) or polyostotic (PFD), involving one or more bones. The term craniofacial fibrous dysplasia (CFD) has been used to describe FD confined to contiguous bones of the craniofacial skeleton.
- PFD accompanied by café au lait spots and endocrinopathies including hyperthyroidism, Cushing syndrome, and precocious puberty, is known as McCune-Albright syndrome (MAS).
- Craniomaxillofacial involvement in FD occurs in 27% of monostotic and up to 50% of polyostotic cases.²
- FD can remain asymptomatic or present with pain, stress fractures, localized swelling, or deformity.
- In the craniofacial skeleton, neurologic impairment can result from nerve compression by expansile FD lesions, potentially leading to blindness, deafness, or spinal cord compression.
- Diagnosis is based on an accurate clinical history, physical examination, and imaging studies.
- Bone biopsy is required to confirm diagnosis.

ANATOMY

- Any bone of the craniofacial skeleton may be affected by FD.

- Although the exact prevalence for each bone is unknown due to the relative rarity of this condition, the maxillary bone is the most frequently involved in several series.^{3–5}
- However, due to the compact and complex nature of the craniomaxillofacial construct, solitary FD lesions of the skull are seldom confined to individual bones, often affecting several contiguous structures.
- As a result, surgical approach and treatment principles are focused on general anatomic regions rather than individual bones.
- Chen et al. classified the craniomaxillofacial region into four major zones based on anatomic location, structures involved, surgical access, importance of reconstruction, and recommended treatment methods (**FIG 1**).⁶
 - Zone 1: Includes the frontal, nasal, ethmoidal, and zygomatic bones as well as the superior, non-tooth-bearing portion of the maxillary bone
 - Zone 2: Parietal, occipital, and squamous portion of the temporal bones
 - Zone 3: Petrous portion of the temporal bones including the mastoid process and the sphenoid bone
 - Zone 4: Tooth-bearing portion of the maxillary bone and the mandible and is separated into zones 4a and 4b

PATHOGENESIS

- FD is a noninherited genetic disease stemming from a postzygotically occurring missense mutation in the GNAS gene.
- Two mutations have been described, resulting from replacement of the arginine residue in codon 201 by either cysteine or histidine.
- The mutation leads to somatic activation of the alpha subunit of signal-transducer G protein (Gs), causing increased levels of cAMP and in turn resulting in high rates of cellular proliferation.⁷
- The abnormal proliferation and high cellular turnover produce poorly differentiated osteoblasts and immature mesenchymal cells, which are deposited within the bone and marrow of FD lesions.
- Elevated cAMP levels have also been demonstrated to upregulate the growth of thyroidal, adrenal, and gonadal cell lines resulting in the characteristic endocrinopathies seen in MAS.

FIG 1 • Subdivision of the craniomaxillofacial region into 4 major zones as described by Chen et al.

NATURAL HISTORY

- The onset and natural evolution of FD can be variable and unpredictable, largely depending on lesion type.
- MFD lesions generally develop in childhood, progress through puberty, and arrest at the end of adolescence once skeletal maturity is complete.
- PFD and MAS variants have been associated with more aggressive growth patterns, demonstrating younger age at presentation and continued tumor growth into adulthood. Up to 90% of these lesions may present before 15 years of age.⁸
- Lesions seen in MAS can continue growing indefinitely, causing progressive disfigurement and functional deficits, requiring prompt surgical

intervention.^{9,10}

- Pregnancy and other settings of estrogen excess such as estrogen therapy have been associated with heightened lesion growth.^{9,11}
- Spontaneous malignant transformation in FD is possible but is rare. It can be observed in MFD, PFD, and MAS forms with reported frequencies ranging from 0.5% to 6.7%.¹²
- Any rapidly developing symptoms such as swelling or pain should raise suspicion of malignant change and prompt the appropriate investigations.
- Exposure to radiotherapy has been demonstrated to be the main risk factor for malignant transformation, being associated with a 44% rate of sarcomatous change. For this reason, radiotherapy is contraindicated in patients with FD.
- Osteosarcoma accounts for the majority of cases, with the remainder consisting of fibrosarcoma, chondrosarcoma, and malignant fibrohistiocytoma.¹³

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient history should include the age at presentation, evolution of the lesion (including periods of rapid growth), and associated symptoms.
- Physical examination should characterize the location of the lesion, its dimensions and any associated contour deformities, facial asymmetry, or functional deficits.
- Although FD is often asymptomatic, presenting as a slowly growing, painless, and nontender swelling, it may be associated with a variety of signs and symptoms that are specific to the anatomic zone affected.
 - Zone 1
 - Hypertelorism, vertical dystopia, and exophthalmos from fronto-orbital involvement and displacement of intraorbital contents
 - Changes in visual acuity and blindness can result from impingement of the optic nerve by lesions invading the anterior cranial fossa
 - Nasal obstruction and recurrent sinusitis can be caused by sinus involvement (**FIG 2**)
 - Facial asymmetry secondary to tumor enlargement
 - Zone 2
 - Headaches and elevated intracranial pressure (ICP) may result from calvarial involvement.
 - Cranial vault asymmetry secondary to tumor growth

- Macrocephaly
- Zone 3
 - Otalgia, fullness, conductive hearing loss, and cholesteatoma formation from external auditory canal (EAC) involvement

FIG 2 • Lateral (**A**) and anterior (**B**) views of a patient with large lower zone 1 fibrous dysplasia. Important nasal airway involvement is seen.

- Vertigo, tinnitus, sensorineural hearing loss, or facial nerve paralysis from invasion of the inner ear and internal auditory canal
- Visual disturbances or blindness with a lesion affecting the sphenoid bone
- Zones 4a and 4b
 - Displacement of teeth, vertical maxillary excess, or malocclusion
 - Patients with lesions neighboring the orbit, namely, those in zones I and III, must be followed with serial visual acuity and visual field measurements to rule out impingement of the optic nerve. Conduction of neuro-ophthalmological studies is also recommended.
 - Given that craniofacial FD can be part of PFD or MAS, the primary clinical assessment should include a full body examination looking for any additional bony lesions, café au lait spots, or findings suggestive of hyperthyroidism, Cushing syndrome, or precocious puberty.
 - When suspected, a multidisciplinary approach with an endocrinologist is

recommended for further investigations and follow-up.

IMAGING

- Radiologic investigation should be conducted in all patients with FD.
- Radiologic appearance of lesions demonstrates three radiologic patterns, namely, pagetoid, sclerotic, and cystic.¹³ Mixed changes also can be seen.
- Standard roentgenography is of limited diagnostic use in FD. Images can demonstrate expanded bone with ground-glass appearance, widened diploic space with displacement of the outer table and sparing of the inner table, cystic skull vault lesions, obliteration of paranasal sinuses, or dental malocclusions.
- High-resolution CT (1-mm cuts) is the preferred imaging modality, providing useful information for diagnosis, follow-up, and surgical planning. Three-dimensional (3D) reconstruction can further assist in surgical planning.
- Images obtained with CT scan:
 - Provide more accurate information regarding lesion size, location, surrounding structures, and potential compression sites (**FIG 3**).
 - Appearance is related to lesion age, with younger lesions appearing more radiolucent and mature lesions appearing more opaque. Ground-glass appearance is seen in established lesions and often represents the best diagnostic clue.⁹

FIG 3 • CT scan of patient with large lower zone 1 fibrous dysplasia. **A.** Sagittal cut. **B.** Coronal cut. **C.** 3D reconstruction.

- Bones affected by FD are usually expanded with intact cortices. Normal corticomedullary differentiation is lost. The margin between abnormal and normal bone is often difficult to identify because the two regions blend into

each other.

- MRI is of lesser diagnostic value than CT. Image appearance is variable, depending on the degree of lucency vs sclerosis.
 - T1- and T2-weighted images generally demonstrate a heterogeneous appearance or decreased signal.
 - Injection of contrast demonstrates variable enhancement, which depends on lesion type.
- Bone scan has a very limited diagnostic role in FD; however, images can provide useful information regarding the presence of secondary lesions in the setting of PFD. Radionuclide uptake is variable.

DIFFERENTIAL DIAGNOSIS

- Paget disease of bone
- Cherubism
- Interosseous meningioma
- Garré sclerosing osteomyelitis
- Cemento-ossifying fibroma
- Craniometaphyseal dysplasia
- Sclerotic metastasis

NONOPERATIVE MANAGEMENT

- Nonoperative treatment in FD can be twofold, including expectant management or medical therapy.
- Expectant management is appropriate in most cases, particularly when lesions are small, slowly growing or static, asymptomatic, and causing minimal functional or aesthetic deficits.
- Regular follow-up and routine annual checkups with CT imaging are required to assess for progression or development of complications.
- Medical therapy is primarily aimed at providing symptomatic relief and can be used as an adjunct to surgery.
 - Acetaminophen and NSAIDs
 - Used for mild bone pain
 - Narcotics
 - Used for more severe bone pain
 - Bisphosphonates
 - Inhibit osteoclast activity, thus improving bone density and potentially

delaying progression of lesions into adjacent structures.⁴

- Reduce pain associated with FD, improve radiologic appearance of lesions, and decrease biochemical markers of bone remodeling (ie, serum ALP).¹⁴
- Typically used in more severe cases such as those seen in MAS.
- The most commonly used agent is pamidronate and is administered intravenously every 6 months (180 mg for adults and 3 mg/kg in children and adolescents).
- Alendronate and zoledronate have also been used.
- Monoclonal antibodies
 - The most commonly used agent is tocilizumab.
 - Decreases IL6 levels and subsequent osteoclast activity by binding to IL6 receptors.
 - Used for pain reduction in patients that fail to respond to bisphosphonate treatment.
- Calcium, phosphate, and vitamin D supplementation can be useful in patients with deficiencies or mineralization defects such as hyperparathyroidism, osteomalacia, and renal phosphate wasting.

SURGICAL MANAGEMENT

- Surgery is the mainstay of treatment for symptomatic FD and is the only definitive treatment modality.
- Because of the complexity of the craniofacial skeleton and the important structures it contains, a multidisciplinary team including otolaryngology, ophthalmology, neurosurgery, and plastic surgery is required.
- The presence of FD alone is not an indication for surgery because many lesions remain static and asymptomatic and are often found incidentally with CT imaging.
- Indications for surgery include the presence of pain not controlled by medical therapy, significant aesthetic deformity, functional deficit (ie, optic nerve compression), rapidly growing lesions, or malignant transformation.
- Surgical approaches are generally divided into shaving/contouring procedures, subtotal/partial resections, and total or wide excisions.
- Total resection of dysplastic bone is the preferred treatment modality (for rapidly growing, malignant, or recurrent lesions), minimizing the risk of recurrence and subsequent need for revisional surgeries. However, total resection may not be feasible, particularly in extensive CFD lesions where wide resection can significantly increase morbidity and the risk of

complications.

- It is of paramount importance to ensure that the defect caused by the procedure does not cause a greater functional or aesthetic deficit than present before surgery. Risks and benefits should be clearly described to patients and families.
- No guidelines exist for surgical management of FD. Treatment should be personalized and guided by the patient's age, lesion characteristics (location, extent, and evolution), and the presence of any functional or aesthetic deficits.
- Bone biopsy must be obtained before surgical intervention when diagnosis is uncertain or when there is concern for malignancy.
- Timing of intervention:
 - Defer surgical procedures until lesion growth subsides and skeletal maturity is attained.
 - Earlier intervention may become necessary if progressive expansion of the lesion causes significant functional, aesthetic, and psychological disturbances to the affected child.
 - Conservative shaving is recommended in these cases. However, patients should be informed that recurrence is possible and further contouring procedures may be required, particularly in cases of PFD and MAS, where continued growth is anticipated.
 - Conversely, if severe deformity is present, which cannot be corrected by contouring, radical excision and reconstruction is indicated. Patients should be made aware that recurrence is possible despite a wide excision.
 - In the adult population, static lesions causing a contour deformity can be appropriately managed by shaving of the lesion. The presence of a functional deficit (such as airway obstruction, oral obstruction or optic nerve compression, etc.) warrants a more radical resection or an en bloc resection, when feasible, and immediate reconstruction.
- Zone 1
 - Represents the most cosmetically sensitive part of the face and is of particular relevance to the craniofacial surgeon
 - Wide excision followed by immediate reconstruction is recommended in cases of significant aesthetic or functional deficit, rapidly growing lesions, malignant transformation, recurrent lesions, and severe pain.
 - The goals of reconstruction include restoration of facial skeletal integrity (reconstruction of horizontal and vertical buttresses), symmetry, globe position, and orbital volume and separation of cranial, orbital, and nasal

cavities.

- Separation between the intracranial and nasal cavities if the anterior cranial base is involved is of paramount importance to prevent infectious complications.
- Reconstruction is preferably performed using split-thickness calvarial bone grafts (SCBG). If the calvarium is unavailable as a donor site due to extensive involvement by FD, split rib grafts or iliac crest bone grafts may be used.
- In cases of incomplete resection of a growing lesion where recurrence is a concern, reconstruction can be temporized with a titanium mesh to match the contralateral normal anatomy.
- Zone 2
 - Represents most of the calvarial region of the cranium, a hair-bearing region of lesser aesthetic importance, where both conservative and radical treatments are possible.
 - Asymptomatic lesions can be adequately treated by shaving in order to restore a symmetric profile.
 - Symptomatic lesions often require wide resection with immediate reconstruction. A variety of materials can be used:
 - Autologous SCBG are preferred when the defect size does not exceed the amount of graft available. Rib grafts and iliac crest grafts are other potential donor sites. Reimplantation of autoclaved resected bone post remodeling has also been described but is not recommended by the senior author.³
 - Cadaveric calvarial allografts.
 - Alloplastic materials such as titanium mesh, methyl methacrylate, porous polyethylene, and polyetheretherketone (PEEK), particularly in the setting of larger defects where the quantity of autologous material is insufficient.
- Zone 3
 - Represents an anatomically complex area containing large vascular structures and multiple cranial nerves.
 - Surgical intervention is challenging, generally avoided, and reserved uniquely for symptomatic cases such as optic nerve compression or EAC stenosis.
 - Optic nerve decompression should be strictly performed in symptomatic cases in an effort to prevent further damage to the optic nerve and deterioration of vision. Improvement of symptoms is not guaranteed.
 - Unroofing of the canal is performed by the neurosurgery team following anterior craniotomy, using an intracranial approach. Simultaneous bilateral

anterior clinoidectomy is often performed.

- Prophylactic decompression based solely on radiographic measurement of optic canal narrowing is contraindicated and has been associated with severe complications such as blindness.¹⁵ Lee et al. have demonstrated that encasement of the optic canal in itself does not correlate with visual loss or results of neuro-ophthalmologic examinations. Hence, the risks of this procedure far outweigh the benefits.
- EAC stenosis: Decompression is performed by the ENT team. The primary goal of the procedure is to restore conductive hearing caused by EAC stenosis.
- Zone 4
 - Represents a functionally important area housing the dentition.
 - The main objective of surgical intervention in this area is to preserve the native dentition.
 - The lesion should be managed with serial debulking procedures during growth to address facial asymmetry.
 - Orthodontic management of malocclusion and orthognathic surgery following arrest of growth provide stable results.¹⁶ Orthognathic surgery within dysplastic bone is challenging as osteotomies must be performed through solid bone.
 - Radical excision should be reserved only for cases of massive bone involvement, severe functional impairment, or malignant degeneration.
 - Free bone graft techniques or free osseous flaps followed by placement of osteointegrated dental implants offer good anatomical and functional recovery.
 - Free flaps are indicated for bony deficits larger than 6 cm.

Preoperative Planning

- The surgeon should discuss the risks and benefits of the procedure with the patient and family.
- All major risks and complications specific to the zone being operated on should be explained, including the possibility of recurrence and need for additional surgery.
- The patient and family should be aware that intraoperative transfusion of blood products may be required in case of bleeding and appropriate consent should be obtained.
- It is recommended to perform a bone biopsy and obtain a final

histopathological diagnosis prior to proceeding with definitive surgery when the diagnosis is uncertain.

- A CT scan of the craniofacial skeleton is essential for preoperative planning. In cases of complex CFD, a 3D model of the craniofacial skeleton is helpful during resection. A mirror-image 3D model of the nonaffected side is helpful during reconstruction by facilitating bone graft reshaping and accurate plate bending.
- In the case of bilateral FD involvement, a 3D model based on CT data matched for age, sex, and race is used in the reconstruction process.
- Magnification loops with headlights can improve visualization during surgery.

Positioning

- The patient is positioned supine with the head centered on a Mayfield head rest.
- The entire head and neck area is prepped; drapes are positioned around the neck, and the head is left exposed to allow optimal intraoperative assessment of symmetry and access to the calvarium if bone grafts are required.
- For extensive lesions involving the nasal or oral airway where wide resection is anticipated, particularly those in lower zone 1, a tracheostomy should be performed by the ENT surgeon before the procedure. This is essential to ensure adequate operative exposure and secure the airway both during the surgery and in the postoperative period, as significant swelling may occur.
- If orotracheal intubation is performed, the endotracheal tube should be secured to the patient's teeth with a 26-Fr stainless steel wire as a precautionary safety measure.

Approach

- The surgical approach and choice of incision are determined by the location of the tumor, the anatomic structures involved, and the goal of the surgery.
- In general, wide resections require wide exposure and a more invasive approach is necessary.
- For shaving or contouring procedure, however, a minimally invasive approach should be privileged to minimize scar burden and avoid compromising facial aesthetics.
- In zone 1, the bicoronal and Weber Ferguson approaches are commonly used for wide resection of lesions involving upper (supraorbital bar and frontal bone

region) and lower zone 1 (naso-orbito-ethmoidal [NOE] and zygomaticomaxillary [ZM] regions).

- A superior gingivobuccal sulcus incision is used for shaving of lesions located in lower zone 1.
- The bicoronal approach allows adequate exposure of the anterior and posterior cranial vault for excision or shaving of lesions involving zone 2.
- Access to lesions in zones 4a and 4b is obtained using superior and inferior gingivobuccal sulcus incisions. In cases of wide resection, submandibular incisions can be used.

TECHNIQUES

■ Surgical Removal of Fibrous Dysplasia in Upper Zone 1

Exposure

- The bicoronal incision is marked in a zigzag fashion at least 5 cm behind the hairline, extending from one auricular helix to the other.
- The hair is combed away from the marked incision line and grouped in bundles, which are twisted and secured with elastic bands.
 - A narrow corridor of hair (1–2 cm) can be shaved directly over the planned incision to facilitate wound closure; however, this is not necessary.
- The incision is infiltrated with a 1% Xylocaine solution containing 1:100 000 epinephrine. Incision is carried out with a no. 10 blade through skin, subcutaneous tissue, and galea, parallel to the orientation of the hair follicles.
 - Monopolar cautery use is minimized to diminish the risk of alopecia.
 - Bipolar cautery is used to perform hemostasis.
- Incision margins are lifted and Raney clips are applied along the anterior and posterior flaps for hemostasis.
- Anteriorly, dissection proceeds in the loose areolar plane until 2 cm above the superior orbital rim.
 - If no pericranial flap is anticipated, the periosteum is incised horizontally from one temporal fusion line to the other, and dissection proceeds subperiosteally until adequate exposure of the nasofrontal and supraorbital

regions is achieved.

- If a pericranial flap may be required, that is, with lesions involving the anterior cranial base, the periosteum is incised at the level of the skin incision and laterally along the temporal fusion lines. It is then dissected off the skull bone using sharp periosteal elevators and surgery proceeds as above (**TECH FIG 1**).
- Laterally, the temporal fusion lines are released. Dissection is carried immediately superficial to the deep temporal fascia until the superficial temporal fat pad is reached.
- At this point, the superficial layer of the deep temporal fascia is incised, and sharp dissection is carried just superficial to the temporal fat pad until the superior aspect of the zygomatic arch and posterior aspect of the lateral orbital rim are reached. Here, the periosteum is incised, and dissection is merged with that described for the anterior segment.
- If access to the orbital roof and medial orbital wall is required, the supraorbital neurovascular bundles must be identified and carefully released from within the confines of the superior orbital notch.
 - If a foramen is present, it is converted into a notch using a 2-mm osteotome by dividing a small bony wedge.
 - Dissection then proceeds subperiosteally until the orbital roof and medial wall are exposed.
- The trochlea of the superior oblique muscle can be released with minimal consequences if required.

TECH FIG 1 • After the anterior scalp has been raised in the subgaleal plane, a pericranial flap is designed. The periosteum is incised posteriorly at the level of the skin incision and laterally along the temporal fusion lines. It is then dissected off the calvarium using sharp periosteal elevators.

- Preserve the medial canthal ligament and lacrimal apparatus unless resection of the lacrimal bone is planned.
- Lateral orbital wall dissection is performed with a Freer while retracting the globe with a malleable. The lateral canthal ligament can be released from the Whitnall tubercle to increase exposure and facilitate supraorbital bar resection.

Resection

- Once adequate exposure has been achieved, the extent of the FD lesion is evaluated. Correlation to preoperative CT imaging and the use of anatomical

landmarks such as the distance to the zygomaticofrontal or nasofrontal sutures can further aid in accurate identification of lesion margins.

- Moderate to severe frontal bone deformities are marked for resection. Mild deformities are burred down to achieve symmetry.
- Resection begins with the frontal craniotomy segment, which is carried out by the neurosurgery team. Bur holes are made at the extremities of the planned resection and on either side of the sagittal sinus. A side-cutting saw with a footplate is used to connect the bur holes.
- The frontal bone is dissected off the dura. Dissection then proceeds inferiorly to expose the anterior cranial base if required.
- Optic nerve decompression is performed at this point by the neurosurgery team when indicated.
- Lesions involving the supraorbital bar are excised using a reciprocating saw. The orbital contents and brain must be protected with malleable retractors at all times to avoid injury.
- Constant irrigation is used to minimize thermal damage to surrounding tissues.
- Warm bone wax, bipolar cautery, and hemostatic agents (ie, Floseal) are used for hemostasis.

Reconstruction

- Once the CFD lesion is completely removed, the anatomical deficit is assessed.
- Preferred reconstruction is carried using SCBG.
- SCBG can be used to reconstruct all necessary segments, including the frontal bone, anterior skull base, and superior orbital rim.
- If all the above structures are involved, the superior orbital rim should be addressed first, followed by the anterior cranial base and the frontal bone.
- Ideally, grafts are outlined on the parietal cranium in the hair-bearing region to optimize symmetry and diminish donor-site morbidity. The graft is usually harvested from the parietal bone of the nondominant hemisphere, at least 1 cm lateral to the sagittal suture. The other hemisphere can be used if additional material is required.
- In cases of unilateral FD involvement, a malleable bent to the shape of the unaffected fronto-orbital bar can be used to help find a harvest site with a curvature most suitable to ensure a symmetric result.

- Strips of bone to be used for reconstruction are outlined and their outer cortex is burred with a 2-mm bur until diploe is reached. An osteotome is used to divide the diploic layer and elevate the outer cortex graft. Utmost care should be taken to avoid breaching the inner cortex. Hemostatic material may be used for the donor site if needed.
- A second option is full-thickness harvest of the outlined cranial bone by the neurosurgeon, followed by ex vivo division of the two cortices on a side table.
- Grafts should span the defect and be secured edge to edge to healthy bone on either end using plates and at least three screws from the 1-mm cranial set (4–5 mm long) on each side.
- Following restoration of the fronto-orbital bar, the anterior cranial base is addressed.
- It is advised to reconstruct the orbital roof with a titanium mesh as bony resorption is known to occur in this region. An overlay of bone graft can be placed if desired by the surgeon, but it is not necessary.
- In the event where the nasal cavity or ethmoid bone has been violated, the pericranial flap is secured over the titanium mesh to ensure a seal between the nasal and intracranial cavities.
- The pericranial flap is secured to the surrounding tissue and bone with a few simple interrupted 4-0 Vicryl sutures.
- It is of extreme importance to repair any dural tear and obtain a watertight seal prior to closure. Tisseel is often used for this purpose.
- Finally, the frontal bone deficit is addressed using the SCBGs, completing reconstruction of the FD defect.
- If the lateral canthal ligament was released, a lateral canthoplasty is performed with a 4-0 Vicryl or a lateral canthoplasty stainless steel suture.
- While protecting the globe, two 1.5-mm holes are drilled through and through, above and below the zygomaticofrontal suture (3 mm posterior to the rim).
- The lateral canthal ligament is grasped with a single hook. Lateral tension on the ligament with the hook should cause lateral movement of the corner of the palpebral fissure. Once properly identified, the lateral canthal ligament is sewn with a figure-of-8 stitch. One limb of the suture is passed through the hole superiorly, while the second is passed inferiorly and then tied.
- A Jackson-Pratt drain is placed on the cranium and the scalp is unfolded.

- Raney clips are removed and hemostasis is ensured.
- A two-layer closure is performed using interrupted 2-0 Vicryl sutures for the galea and a running 4-0 nonresorbable suture or staples for the skin.
- Antibiotic ointment is applied along the incision and a lightly compressive head dressing is placed.

■ Surgical Removal of Fibrous Dysplasia in Lower Zone 1

Exposure

- A subcranial approach using a Weber Ferguson incision is preferred and should be used for NOE and ZM lesions found below the nasofrontal suture and sparing the cribriform plate.
- Involvement of the cribriform plate will require the addition of a bicoronal incision, elevation of a pericranial flap as described above, and frontal craniotomy to ensure an adequate protection to the brain and a full seal between the brain and nasal cavities.
- A tracheotomy should be performed by the ENT surgeon for patients with extensive NOE lesions where wide resection is anticipated, particularly if the nasal airways are involved.
 - This is essential to ensure adequate operative exposure and secure the airway both during the surgery and in the postoperative period, as significant swelling may occur.
- The incision is marked along the ipsilateral philtral column, around the nasal ala, and superiorly along the nasofacial groove (**TECH FIG 2**).
- Markings can extend laterally along a subciliary incision line, which can be used if additional exposure is required.
- Cupid's bow is marked and tattooed to ensure exact reapproximation during closure.
- The incision line is infiltrated along its length with 1% Xylocaine with epinephrine 1:100 000.
- Using a no. 10 blade, the skin is incised along the nasofacial groove and around the nasal ala until the periosteum is reached.
- The superior lip is cut through and through.
- Intraorally, a superior gingivobuccal incision is made 5 mm buccal to the

sulcus in order to preserve a mucosal cuff for closure.

- Mucosa, submucosa, and muscles are divided directly down to bone.

TECH FIG 2 • Weber Ferguson incision markings on the patient in **FIG 2**.

- The flap is then elevated using a no. 9 periosteal elevator in the subperiosteal plane, and the hemiface is retracted superolaterally. Identify the infraorbital nerve (ION), which is usually found 4 to 7 mm inferior to inferior orbital rim in line with the midpupil.
- The ION should be preserved if the lesion's location is medial to it. For more extensive lesions, the ION is scarified and dissection proceeds laterally until the FD is fully exposed.
- A subciliary incision can be added for further access. The skin is incised longitudinally 2 mm below the lash line. The pretarsal and some of preseptal orbicularis oculi muscle should be preserved to prevent postoperative ectropion.
- Sharp subcutaneous dissection is performed to raise the inferior skin flap over the muscle along the length of the incision. The muscle is transected at the level of the inferior orbital rim, and dissection proceeds until the periosteum to join the plane of the flap raised in the steps above.
- The arcus marginalis is released.
- The orbit is dissected with a Freer in a subperiosteal plane while protecting the globe with a malleable.

Resection

- With the entire lesion exposed, two approaches are available for complete excision (**TECH FIG 3A**).
- First, an en bloc resection can be performed with osteotomies carried peripheral to the FD lesion. The extent of resection varies depending on the size and location of the FD.
- For large and extensive inferior zone 1 lesions as demonstrated in this patient, resection begins superiorly by performing an osteotomy at the level of the nasofrontal suture using a reciprocating saw (**TECH FIG 3B**).
 - The position of the cribriform plate should be determined to avoid violating the intracranial cavity.
 - The osteotomy extends medially across the lacrimal and ethmoid bones and then extended laterally along the orbital floor using a 3-mm osteotome until the inferior orbital fissure is reached.
 - The globe is retracted and protected at all times with a malleable retractor.
 - Frequent communication between the anesthesiologist and surgeon is maintained to monitor for the oculocardiac reflex.
 - The zygoma is cut at the level of the body or arch with a reciprocating saw.
 - The osteotomy proceeds laterally along the lateral wall of the maxilla.
 - Inferiorly, the osteotomy should be at least 3 mm above the dental roots (as measured from preoperative CT or 30 mm from the crown of the canine) to preserve the native dentition, as reconstruction of this region is cumbersome, particularly in a growing child.
 - Osteotomy of the vomer is performed with a 5-mm osteotome from the nasofrontal suture, in a 45-degree posterior angle aiming toward the junction of the soft-hard palate.
 - The surgeon's nondominant hand is placed on the palate to prevent a full-thickness laceration.
 - Constant irrigation is performed during osteotomies to avoid thermal injury to the bone.
 - Once all osteotomies have been completed, the FD lesion is removed en bloc and hemostasis ensured using bipolar cautery, warm bone wax, and hemostatic agents such as Floseal.
- A second approach used by the senior author for very large lesions consists of centrally coring out the lesion and separating the FD from healthy bone along a well-defined plane. This technique is preferred with lesions abutting the cribriform plate as it may prevent the addition of an intracranial approach by limiting the extent of resection.

TECH FIG 3 • A. Raising of the flap is complete and the fibrous dysplasia lesion is completely exposed. **B.** Osteotomy lines for en bloc resection of a large bilateral lower zone 1 FD lesion as seen in our patient. The osteotomy begins superiorly at the level of the nasofrontal suture and extends medially across the lacrimal and ethmoid bones and then laterally along the orbital floor until the inferior orbital fissure. The zygoma is cut at the level of the body or arch, and the osteotomy proceeds laterally along the lateral wall of the maxilla. Inferiorly, it is important to keep the osteotomy at least 3 mm above the dental roots. **C.** After central coring of the lesion, a surgical plane is sought between the FD and healthy bone. **D.** Once

revealed, dissection proceeds along this distinct layer between the FD and healthy bone until the exophytic part of the lesion is removed (*arrow*) and the origin of the lesion identified. **E. Complete removal of FD lesion.**

- The exophytic core of the lesion is debulked using a reciprocating saw starting centrally and proceeding concentrically outward until the outer margin of the lesion is approached.
- At this stage, a surgical plane is sought between the FD and healthy bone. When present, the shell of the FD can collapse inward, revealing a distinct layer between the FD and healthy bone (**TECH FIG 3C,D**).
- Excision proceeds along this plane until the exophytic portion of the lesion is removed and the origin of the lesion identified. The latter is then burred until no dysplastic bone remains (**TECH FIG 3E**).
- In this case, the approach allowed removal of the FD lesion while sparing the cribriform plate and avoiding an intracranial approach.

Reconstruction

- Reconstruction of the midface must re-establish the normal skeletal anatomy. The horizontal buttress, vertical buttress, and nasal bone are essential to obtain normal projection and width of the midface.
- Reconstruction of the midface skeleton is performed preferentially with cranial bone graft. The bone grafts are harvested from the parietal cranium through a coronal or a sagittal incision, as described above.
- A perfected computer-aided design (CAD) 3D model of the patient's craniofacial skeleton can be ordered and printed with the midface segment virtually reconstructed (corrected to normal anatomy for patient age, race, and sex or a mirror image of the normal side when possible; **TECH FIG 4A**).
- The 3D model is used to shape the bone graft, bend the titanium plate (1.5-mm midface system), and facilitate positioning of the construct (**TECH FIG 4B**). This method of reconstruction increases symmetry and improves accuracy.
- Because of the expansile nature of this lesion and this patient's history of 10 previous debulking procedures, a 15 × 15 cm titanium mesh (1.0 mm thick) was bent on the corrected 3D model preoperatively.

- Independent mesh panels were used for both hemiface regions. The panels were sterilized for reconstruction.
- Bony construction was performed using large premolded titanium mesh, which was prepared prior to surgery and sterilized. This was done in order to preserve autologous reconstruction options in case of future recurrence.
- The prebent midface mesh panels were fixed to the zygoma, nasofrontal suture, and maxillary bone with multiple 4- to 6-mm screws (**TECH FIG 4C**).
- The orbital mesh was attached to the midface mesh with 28-gauge wires.
- An opening was made in the mesh to replicate the piriform aperture.
- For reconstruction of the orbital floor, titanium mesh was bent in a lazy S shape with extension to reconstruct the medial orbital wall. The mesh was fixed medially and superiorly to the frontal bone with 4-mm screws and laterally to the zygomatic bone.
- The medial canthal ligament is grasped with a 4-0 PDS (or canthal wire suture) in a figure-of-8 pattern and passed in a superior oblique vector across the mesh. A similar step is performed on the contralateral side. Both ends are tied together.

TECH FIG 4 • A. 3D CT perfected model with a virtually reconstructed midface segment corrected to normal anatomy for patient age, race, and sex. **B.** Once printed, the perfected 3D model is used to bend the titanium plates to the desired shape. **C.** Titanium meshes with medial extensions bent in a lazy S shape are used to reconstruct the orbital floors and medial walls bilaterally. These are fixed medially and superiorly to the frontal bone and laterally to the zygomatic bone. Two prebent midface mesh panels are then fixed to the zygoma, nasofrontal suture, and maxillary bone. **D.** Placement of SCBGs for reconstruction of large bilateral lower zone 1 defects. **E.** Closure of Weber Ferguson incision. Image of

patient in early postoperative period. **F.** Lateral view of patient in immediate postoperative period demonstrating adequate midface projection.

- The midface periosteum was suspended to the orbital rim with two 3-0 Vicryl sutures positioned at the level of the pupil and lateral canthus to prevent midface ptosis.
- A lateral canthoplasty was performed.
- Lacrimal duct system reconstruction was not performed but was delayed until a later stage.
- Strips of SCBG were used to reconstruct the orbital rim. The bone grafts were fixed with the 1.0- or 1.5-mm plating system using 4-mm screws.
- The orbital floor and medial wall are then reconstructed as described above with a titanium mesh or bone graft.
- The zygomatico-maxillary and nasomaxillary buttress are then reconstructed similarly with bone graft. These grafts are fixed with the 2.0-mm plating system.
- A cantilever bone graft was used to reproduce nasal contour and projection, secured to the frontal bone using miniscrew fixation (**TECH FIG 4D**).
- After ensuring hemostasis, closure begins with resuspension of the midface to avoid facial ptosis by reattaching the periosteum of the midface. At least two suspension sutures should be utilized, one at the level of the pupil and the second at the level of the lateral canthus. The sutures grasp the periosteum 3 cm inferior to the pupil and lateral canthus and suspend them to the orbital rim using 3-0 Vicryl sutures.
- The WF flap is then closed using standard two-layer closure using 3-0 Vicryl and 4-0 nylon (**TECH FIG 4E,F**).
- A lateral tarsorrhaphy suture is considered if the patient is likely to develop chemosis.
- Antibiotic ointment is placed over the incision line.

PEARLS AND PITFALLS

History and physical findings	■ Complete history and physical examination should be performed in order to differentiate between the various forms of FD (MFD, PFD, MAS). ■ Visual examination, including neuro-ophthalmological studies, should be obtained for lesions in zones 1 and 3.
Preoperative	■ High-resolution CT scan is the preferred imaging modality to plan for FD resection. 3D reconstruction can further assist in planning. ■ Bone biopsy and definitive pathological diagnosis are recommended prior to definitive surgical treatment when malignant fibrous dysplasia is suspected. ■ Medical therapy with bisphosphonates (ie, pamidronate) can be used as an adjunct to surgery, providing symptomatic relief for painful lesions.
Surgical management	■ Surgical management is the only definitive treatment modality and should be reserved for lesions causing pain unrelieved by medical therapy, significant aesthetic deformity, functional deficit (ie, optic nerve compression), rapidly growing lesions, recurrent lesions, or malignant transformation. ■ Surgical treatment should be deferred until growth of the lesion subsides and skeletal maturity. Shaving is recommended for growing lesions. ■ Optic nerve decompression should only be performed for symptomatic cases. Prophylactic decompression can be associated with severe complications such as blindness.
Technique	■ Goals of reconstruction include restoration of facial skeletal integrity, projection and symmetry (reconstruction of horizontal, vertical buttresses and nasal bone), globe position, and orbital volume. ■ A pericranial flap should be planned when anterior cranial fossa resection is planned in order to separate the nasal and cranial cavities. ■ Titanium mesh reconstruction should be used in orbital roof and anterior cranial fossa reconstruction as late bony absorption occurs with split cranial bone graft. ■ For large lesions, particularly in lower zone 1, central coring of the lesion should be attempted prior to en bloc resection, as a distinct plane may exist between FD and healthy bone, allowing to minimize the resection and potentially sparing an intracranial approach. ■ Inferior osteotomy for lesions in lower zone 1 should remain 3 mm above the dental routes when possible to preserve the native

dentition.

- The orbital contents and brain must be protected at all times using a malleable. Continuous irrigation should be used when using the reciprocating saw around these structures to avoid thermal injury to bone.
- Immediate reconstruction with SCBG is preferred; however, in cases of incomplete resection of growing lesions where recurrence is a concern, reconstruction can be temporized with a titanium mesh.

Postoperative

- Careful long-term postoperative follow-up is essential to survey recurrence. Annual CT scanning is recommended.

POSTOPERATIVE CARE

- ICU care is essential for intracranial resection or when airway swelling is expected.
- Visual assessment in the first 48 hours is performed every 4 hours while awake.
- Postoperative antibiotics for at least 24 hours are essential in the setting of intracranial resection.
- Lateral tarsorrhaphy sutures are removed when chemosis has resolved.
- Peridex mouth wash (TID and with oral intake) and teeth brushing are important in the 1st week following surgery.

OUTCOMES

- Careful long-term postoperative follow-up is essential to survey recurrence. **FIG 4** shows the patient 5 months following surgery.
- Annual clinical assessments and CT scanning are recommended.
- In a large series of pediatric CFD, the mean time to recurrence has been demonstrated to be 2.25 years.
- Recurrence rates are generally low and depend on several patient-specific and treatment-specific factors:^{15,16}
 - Time of intervention: Surgery before skeletal maturity is associated with a higher rate of recurrence.
 - Type of intervention: Debulking is associated with a higher rate of recurrence when compared to wide excision and reconstruction.
 - Type of lesion: Highest rates of recurrence are seen in patients with MAS, followed by PFD and MFD.

- Serum ALP has been demonstrated to be a useful marker to monitor for disease recurrence.
- Rising levels can be useful when malignant transformation is suspected.

FIG 4 • Anterior (**A**) and lateral (**B**) view of patient 1 year following surgery.

COMPLICATIONS

- General complications associated with operative management of FD in the craniofacial skeleton include bleeding/hematoma, surgical site infection, facial asymmetry, and recurrence.
- Zone 1
 - Superior sagittal sinus laceration
 - Dural tear/brain injury
 - Globe injury
 - Anterior cranial base fracture and communication between intracranial and nasal cavities
 - Meningitis
 - Optic nerve injury
 - Infraorbital or supraorbital nerve injury
 - Midface ptosis
 - Ectropion
 - Alopecia
- Zone 2
 - Superior sagittal sinus laceration
 - Dural tear/brain injury

- Zone 3
 - Optic nerve injury
 - Temporal hollowing
- Zone 4
 - Dental root injury
 - Inferior alveolar nerve injury

Section V: Skull Defects

47 Autologous Bone Harvest to Correct Open Skull Defects

CHAPTER

Michael R. Pharaon

DEFINITION

- Skull defects can be congenital or acquired.
 - Congenital defects can be the result of encephalocele, cutis aplasia, or foramina parietalia permagna.
 - Acquired defects can be the result of trauma, tumor or tumor extension, osteomyelitis, bone flap loss, or persistent skull defects following surgery or prior cranioplasty.
- Skull defects can result in lack of bony protection to the brain, contour deformities resulting in visible defects, as well as visible pulsatile regions on the face that can cause significant body image concerns for the patients.^{1,2}

ANATOMY

- Layers of the scalp include the skin, galea aponeurosis, followed by a layer of loose connective areolar tissue, and the pericranium (periosteum).
- The mature skull consists of three distinct layers, the outer table, medullary cavity, and inner table.
- Deep to the skull is the endosteal layer of the dura mater.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Large skull defects are noticeable—particularly on the frontal and anterior temporal regions anterior to the hair line—due to the associated contour deformity. They may be associated with pulsatile movement of the overlying scalp.

- Skull defects posterior to the hairline may be palpable on exam, though not visually detectable.
- Bulging of soft tissue over a skull defect may be an indication of increased intracranial pressure. This is a particularly important finding in the setting of multisuture cranial synostosis with residual skull defects following prior cranioplasty and indicates the need for cranial vault expansion in addition to reconstruction of the skull defect.
- The soft tissue in the region of the bony defect should be evaluated. Evaluation should include assessment of prior surgical scars and evidence of previous radiation injury to the skin.
- The volume and contour of the soft tissue envelope over the calvarial defect should be evaluated. This is particularly important if the calvarial vault will undergo significant expansion with bony reconstruction. Expansion may result in inadequate soft tissue coverage over the bone grafts.¹

IMAGING

- A CT scan of the head and maxillofacial skeleton with fine cuts should be obtained for preoperative planning purposes.
- 3D reconstructions of the calvarium are used to visualize the defect and plan for reconstruction (**FIG 1**).

SURGICAL MANAGEMENT

- The goals of calvarial vault reconstruction are to provide adequate protection for intracranial structures and to re-establish an aesthetic cranial contour.

Preoperative Planning

- Preoperative CT scan with 3D reconstruction images should be reviewed.^{1–3}
- Location and size of the bony defect should be assessed.
- An appropriate calvarial donor site should be identified. Adequacy is determined by the presence of sufficient bicortical calvarial bone.
- If inadequate calvarial bone is available, iliac crest or split rib grafts should be considered.

Positioning

- The patient is placed in a supine or prone position, depending on location of the calvarial defect. A gel-padded Mayfield head rest (horseshoe) is positioned based on the location of the defect and bone graft donor site.

- If the patient is positioned prone, careful padding is required to avoid pressure on the globes.
- If a posterior calvarial donor site is planned for anterior bone grafting, the patient may require closure of the donor site and repositioning for access to the anterior calvarium.

Approach

- Surgical approach to the calvarial vault is typically performed via a bicoronal incision, which provides adequate access to the skull defect as well as to potential bone graft donor sites.
- A bicoronal incision can be modified based on prior surgical scars or if a noncalvarial donor site is planned.
- Transection of prior scars should be avoided because it compromises blood flow to the scalp.
- Iliac donor sites can be approached through either an anterior or a posterior approach.¹
- Split rib grafts are approached via a limited thoracotomy incision.⁴

FIG 1 • Preoperative 3D CT scans of a patient with Saethre-Chotzen. **A.** The AP view demonstrates a right forehead skull defect and a left orbital rim defect. **B.** Right lateral view demonstrates the right lateral forehead defect. The parietal skull demonstrated

adequate thickness for split calvarial bone graft harvest.

TECHNIQUES

■ Preparation of the Skull Defect Site

- If no scalp scars are present, a zigzag bicoronal incision is marked.
 - If a pre-existing bicoronal scar is present, it is used as the incision (**TECH FIG 1**).
- A 1-cm-wide area of hair is trimmed on either side of the proposed incision.
- The hair is parted and secured with rubber bands.
- Along the incision line, the scalp is injected with 0.25% Marcaine with epinephrine, (1 cc/kg). If an infant is undergoing the procedure, the local anesthesia can be diluted with normal saline at a 1:1 ratio to increase the total volume injected.
- Bicoronal incision is made with Colorado tip Bovie cautery or scalpel.⁵ Scalp flaps are elevated in the subgaleal plane. In the region of the bony defect, avoid injuring the dura.
- In the region of planned osteotomies, including regions of split calvarial bone graft harvest, dissection is performed in the subperiosteal plane.
- With neurosurgery assistance, the soft tissues and dura are dissected away from the bony defect, and bone edges are debrided as necessary prior to harvesting bone graft material.

TECH FIG 1 • A prior zigzag bicoronal incision was used to access the calvarial vault. Note that this patient required hardware removal in addition to bone grafting to correct areas of bone reabsorption.

■ Split Calvarial Bone Graft

- The author prefers harvesting a full-thickness calvarial bone graft from the parietal calvarium with the assistance of neurosurgery (**TECH FIG 2A**).^{1,3}
- Once the full-thickness bone graft is harvested, it is split on the back table with the use of a reciprocating saw and a thin osteotome.
- The author prefers using the reciprocating saw along the borders of the full-thickness bone graft; the subsequent cleavage of the inner and outer tables is accomplished with the osteotome.^{1,3}
- If a large bone graft is harvested, it can be divided into smaller strips to facilitate separation of the inner and outer tables.
- The outer table is fixated at the donor site with plates and screws (**TECH FIG 2B,C**).
 - In the pediatric population, fixation is performed with resorbable plates and screws.⁶ In skeletally mature patients, either resorbable or titanium plates

and screws can be used to provide fixation.

- The inner table bone graft is then used to cover the calvarial defect and secured similarly.
- The scalp is reapproximated with transgaleal interrupted Vicryl sutures. (Typically, the author uses 3-0 and 4-0 Vicryl for pediatric patients and 2-0 and 3-0 Vicryl for adults.) The skin is reapproximated with a 5-0 Monocryl running baseball stitch or staples.
- The hair is washed with sterile saline and shampoo.
- The incision is dressed with bacitracin ointment followed by Xeroform sterile cotton fluffs, a sterile blue towel folded as a turban, and covered with burn stretch netting for gentle compression.

TECH FIG 2 • A. The inner (*left*) and outer (*right*) tables of split parietal calvarium were used to reconstruct the anterior calvarium. **B.** AP view CT scan demonstrating the reconstructed forehead following bifrontal craniotomy with rotation and readvancement of the left forehead with split calvarial bone grafting. **C.** Bird's eye view CT scan demonstrating the right parietal split calvarial bone graft donor sites and recipient sites in the left temple and orbital rim.

■ Iliac Crest Bone Graft

- The skin immediately lateral to the anterior superior iliac crest is retracted medially.
- A skin incision is then made over the iliac crest, with dissection through the subcutaneous tissue until the external oblique muscle fascia is encountered. The external oblique insertion is elevated in the subperiosteal plane from the iliac crest.
- On the internal iliac fossa, the iliacus muscle is elevated in the region of the planned bone graft harvest.
- Osteotomies are made with a reciprocating saw through a single cortex of the iliac bone. A right-angle reciprocating saw is used to cut the posterior aspect of the bone graft (**TECH FIG 3**).¹
- An osteotome is used to separate the medial cortex from the cancellous portion of the iliac bone.
- Thrombin-soaked Gelfoam is placed over the exposed cancellous bone. The iliacus muscle is resuspended over the iliac crest to the external oblique and tensor fascia lata.
- The subcutaneous tissue and skin is closed with resorbable sutures and the incision covered with Dermabond.

TECH FIG 3 • Harvest of iliac crest bone graft from iliac fossa via an anterior approach. Bone is harvested from the inner table with a variable amount of

cancellous bone.

■ Rib Graft

- The patient is placed in the supine position for smaller sized rib grafts. For larger grafts, the patient is placed in the lateral thoracotomy position.⁴
- The incision is planned at the level of the inframammary fold and extended posteriorly based upon the size of the graft.
- The incision is extended to the sixth rib. The periosteum is incised longitudinally and the rib bluntly dissected circumferentially from the periosteum. A rib periosteal stripper is used to release the posterior rib periosteum, without violation of the pleural space (**TECH FIG 4**).
 - Avoid injury to the subcostal neurovascular bundle.
- At the posterolateral aspect of the graft, the rib is divided with rib cutters.
- The rib is then elevated from lateral to medial ensuring that the pleura remains intact. Anteriorly, the rib is also divided with a rib cutter.
- The pleural lining is inspected for pleural tears. The dissection pocket is filled with sterile saline, and a Valsalva maneuver is performed to determine whether an air leak is present. If an air leak is noted, the pleura is repaired over a red rubber catheter. The catheter is removed at final wound closure during a Valsalva maneuver provided by the anesthesiologist. If no air leak is present, then the periosteum is reapproximated with 2-0 Vicryl suture, and the remaining wound is closed.
- If an additional rib is required, the fourth rib is harvested through the same incision in a similar manner. The fourth rib is harvested lateral and posterior to the breast.
- The soft tissues are then reapproximated with layered wound closure.

TECH FIG 4 • A. Rib graft harvest generally targets the sixth rib. **B.** A rib periosteal stripper is used to separate the posterior periosteum from the rib. The periosteum is repaired after removal of the rib.

PEARLS AND PITFALLS

CSF leak

- Dural tears need to be identified at the time of closure and repaired.
- Failure to recognize a CSF leak may lead to significant wound healing problems and necessitate return to the operating room.

Operative planning

- Careful preoperative planning is required to determine the size of required bone graft and donor-site availability.

Pneumothorax

- Postoperative chest x-rays are required if the pleural space is violated and repaired.
- Failure to treat an air leak following rib harvest can result in a postoperative tension pneumothorax.

Adjacent rib harvest

- Failure to harvest every other rib can result in paradoxical chest wall movement with inhalation.
- Leave an intact rib between harvested ribs (ie, fourth and sixth ribs with fifth rib intact).

POSTOPERATIVE CARE

- Perioperative systemic antibiotics are discontinued after 23 hours.
- The dressing is removed on postoperative day 2.
- Antibiotic ointment is continued on the incision for 1 week.
- The patient is allowed to shower on postoperative day 2.
- No swimming or contact sports for 4 weeks following surgery.

OUTCOMES

- The majority of patients undergoing reconstruction for calvarial defects with autologous bone reconstruction have satisfactory functional and aesthetic outcomes.
- Sahoo et al. demonstrated fewer complications with autologous reconstruction compared to all plastic materials.³

COMPLICATIONS

- Recipient site complications:⁷
 - Bone infection
 - Bone resorption⁸
 - Contour deformities
 - Recurrent skull defects
 - Prominence or exposure of titanium hardware
- Donor site complications:⁷
 - Seroma
 - Hematoma
 - Pneumothorax (rib)
 - Contour deformities
 - Paresthesias secondary to nerve injury
 - Gait disturbances
 - Fracture
 - Hernia
 - Injury to internal organs

Section VI: Frontal Sinus

48

Frontal Sinus Cranialization

CHAPTER

Mohamad Masoumy, Prasanth Patcha, Robert C. Dinsmore,
and Jack C. Yu

DEFINITION

- Cranialization refers to the removal of the posterior table of the frontal sinus with occlusion of the inlet into the frontonasal ducts and allowing the neural structures, mainly frontal lobes of the brain and the intact dura, to move directly posterior to the anterior table of the frontal bone.
- Cranialization is performed in patients with frontal sinus fractures when the frontonasal duct drainage is interrupted and cannot be reconstituted even with intubation or endoscopic salvage procedures.^{1–4}
- Once frontonasal duct integrity is lost, the two surgical options are cranialization and obturation. Obturation is defined as filling of the frontal sinus with grafts, often consisting of adipose tissue. Both cranialization and obturation require the complete removal of sinus mucosa and closure of the cephalic part of the frontonasal duct with two key differences.
- In obturation, the posterior table must be preserved or restored. If there is any concern for CSF leak, remove the posterior table and inspect the dura for injury. During cranialization, the posterior table must be resected.

FIG 1 • A. Frontal sinuses in situ. **B.** Parasagittal section, normal anatomy. **C.** Supraorbital foramina (*arrows*) mark the lateral boundaries of the frontal sinus. The anterior table has been partially removed from the left half of the frontal sinus on this model. **D.** Anterior table of frontal sinus reflected.

- In obturation, bone, fat and other tissue are used to fill the frontal sinus space. In cranialization, this space is ultimately occupied by the brain and allows for brain edema without increased intracranial pressure; as the brain moves into this space, the anterior table of the frontal bone becomes the only bony layer

of the inferior anterior cranial vault.³

ANATOMY

- The frontal sinus is located in the lower 10% to 15% of the forehead and the width ranges from 2 cm to more than 10 cm. The supraorbital foramen can serve as an approximate indicator of the lateral extent of the frontal sinus. AP dimensions measure approximately 15 mm at the base with a gradual taper cephalically, extending 20 to 30 mm with a variable, scalloped border. Often a complete bony septum separates the sinus cavity into left and right compartments (**FIG 1**).
- Mucus-secreting respiratory mucosa completely lines the internal surface of the frontal sinus. The mucous drains through a funnel-shaped outlet leading into the frontonasal duct, which opens in the infundibulum of the middle meatus of the nose.
- Behind the posterior table is the triangular bony anchor of the falx cerebri, crista galli, bordered laterally by the cribriform plate of the ethmoid bone. The olfactory fibers exit the cranium into the most cephalic part of the nasal cavity to provide special visceral afferent innervations. Dural sleeves cover these olfactory fibers. In trauma, the laceration of these dural sleeves by bone fragments leads to CSF rhinorrhea.
- The anterior cranial fossa directly above the nasal cavity is and must remain completely sterile. Thus, the surgeon's primary objective in caring for patients with frontal sinus fractures is to restore this secure separation of the nose from the intracranial space to avoid infection from nasopharyngeal flora.

PATHOGENESIS

- During sudden compressive loading of the forehead, as in a blunt frontal impact, the anterior table will deform rapidly. If the strain exceeds the ultimate tensile strain of the bone, it fractures. Fracturing absorbs kinetic energy and greatly reduces force transmission, protecting the frontal lobe of the brain.
- Higher energy impacts can extend fractures across the apex and the floor of the sinus into the posterior table and the frontonasal duct.²
- Frontal sinus trauma resulting in severe and extensive fractures of the anterior and posterior tables frequently involves the frontonasal outflow tract.
- If there is greater than 25% disruption of the posterior table, cranialization should be considered.⁵
- Another indication for cranialization is for closure after anterior skull base

tumor surgeries or other craniotomy procedures involving the anterior vault.

NATURAL HISTORY

- Significant frontal sinus injuries involving the posterior table or frontonasal duct can lead to the complications of mucocele, mucopyocele, osteomyelitis, late CSF leak, meningitis, and cerebral abscess. Management via cranialization during the initial fracture can help to avoid these sequelae.^{1–8}

PATIENT HISTORY AND PHYSICAL FINDINGS

- Blunt and penetrating traumas are often the cause of frontal sinus fractures. The patient may have a history of recent or remote trauma (**FIG 2**). In the setting of remote trauma, a high level of suspicion must be maintained for such sequelae as mucocele/mucopyocele, CSF leak (early or late), and osteomyelitis of the frontal bone.
- At the time of evaluation, assess contour abnormalities of the forehead, brow, and frontonasal region. Document presenting symptoms such as paresthesia, numbness, or paralysis. Furthermore, search for associated injuries of other facial regions, the cervical spine, brain, eyes, cranial nerves, and the major neck vessels. Advance Trauma Life Support protocols should always be followed.
- The initial note should document the patient's neurological status, olfaction, visual acuity, extraocular movements, pupil size and reactivity, rhinorrhea if present, maxillary and mandibular stability, occlusion, facial movements, and sensation. Cervical tenderness is important, especially if it is out of proportion to radiological or clinical findings. Lateral neck pain could represent carotidynia, a sign of carotid artery injury.

IMAGING

- CT imaging with thin-cut axial, coronal, sagittal with 3D reconstructions is the radiologic gold standard. These images evaluate both anterior and posterior table frontal sinus fractures as well as associated intracranial, facial, and spinal injuries (**FIG 3**).
- Some surgeons advocate intraoperative navigation using available CT data with a stable fiduciary and infrared multicamera system. The advances in stealth technology have rendered such guidance tools easier to use as well as simpler and faster to set up.
- 6-foot Caldwell x-ray with a coin reference is more of a historical relic to help

map the boundaries of the frontal sinus.³⁻⁵

FIG 2 • Massive craniofacial wound from shotgun blast at close range.

FIG 3 • **A.** 3D CT reconstruction demonstrating comminuted facial fractures with concomitant frontal sinus injury from the shotgun blast. **B.** Axial CT demonstrating massive injuries to the anterior and posterior tables of the frontal sinus with segmental bone loss. **C.** Axial CT image showing destruction of the frontonasal duct.

DIFFERENTIAL DIAGNOSIS

- Frontal sinus fractures need to be further characterized using the following variables to best guide treatment:
 - Extent of injury to the anterior and posterior tables including severity of displacement and comminution
 - The status of the frontonasal duct

- Dura integrity
- Status of the brain (see **FIG 3B,C**).^{3,4,6,7}

NONOPERATIVE MANAGEMENT

- Advise all patients to avoid pressurization of the nasal cavity and the paranasal sinuses. Instruct patients to sneeze through an open mouth and refrain from nose blowing to help prevent pressurization.
- Nonoperative management is not applicable for injuries that disrupt drainage from the frontal sinus via the frontonasal ducts, as inadequate drainage will inevitably result in mucocele formation and eventual infection.
- Posterior table fractures that are minimally or nondisplaced with intact frontonasal tract can be treated with simple ORIF of the anterior table if it is displaced. If the anterior table is not displaced, treatment with close observation is appropriate. If complications with frontal sinus drainage develop, salvage/drainage procedures can be performed endoscopically.^{3,4,6,7}

SURGICAL MANAGEMENT

- Main goals for cranialization
 - Removal of the posterior table
 - Repair of any dural lacerations
 - Removal of all sinus mucosa
 - Plugging the frontonasal outflow tract to create a secure barrier between the nasopharynx and the anterior cranial fossa
 - Correction of the frontal contour deformity¹⁻⁸

Preoperative Planning

- Obtain the necessary consults (neurosurgery, otolaryngology).
- Review risks (including acute and long-term complications), benefits, and expectations with patients on the day of surgery.
- Ensure coordination with the neurosurgical team and proper instrument availability for osteotomy and fixation techniques.

Positioning

- The patient is positioned supine with oral intubation and the table rotated 180 degrees.
- The patient's body can be tilted upward (30 to 40 degrees) and the neck retroflexed 15 to 20 degrees (when clinically feasible).

- The surgical preparation and draping should include the head and right lateral thigh for possible fat graft harvest.

Approach

- A coronal incision is used with various modifications taking into consideration hair pattern and density and exposure needs.

TECHNIQUES

■ Preparation and Exposure

- The hairline in the forehead with lateral extension down to the preauricular areas is marked before shaving the hair back 1 to 2 cm.
- A standard coronal incision can be used for individuals with receding hairlines or baldness.
- Inject the planned incision site with 0.25% bupivacaine with 1:200 000 epinephrine.
- The entire face and the scalp are prepped and draped.
- Prep the abdomen if subcutaneous fat is to be used as graft.
 - Other potential donor sites are the right anterosuperior iliac crest with extension to lateral thigh or the right hemithorax if cortical-cancellous bone and fascial grafts are needed (**TECH FIG 1A**).
- The planned coronal incision is made sharply or with fine needle tip electrocautery to reduce bleeding.
 - To ensure sufficient length for the pericranial flap, the scalp can be dissected posteriorly in the subcutaneous plane for a significant length (6 to 8 cm or more if needed) before cutting through the galea while preserving the pericranium (**TECH FIG 1B**).
 - The anterior dissection then proceeds within this relatively avascular subgaleal, suprapariosteal plane until the superior orbital rims.
- The pericranial flap of the desired width and length is then marked, incised, and raised, from posterior toward the orbits.
 - Elevate the pericranial flap by incising the periosteum at the superior orbital rims. During this elevation, the supraorbital and supratrochlear neurovascular bundles located at the medial third of the superior orbital rim

must be carefully preserved as they provide the blood supply to the pericranial flap (**TECH FIG 1C**).

- If complete mobilization of the superior orbital nerve is needed, a 2-mm osteotome can be used to convert the foramen to a notch by cutting the most caudal part of the foramen medial and lateral to the neurovascular bundle.

The neurosurgery team then performs frontal craniotomy to provide access to the anterior cranial fossa; the frontal bone flap is a potential source of split-thickness cranial bone grafts (**TECH FIG 1D**).⁴

TECH FIG 1 • **A.** Planned incision for optimal exposure. **B.** Extent of planned pericranial flap that is anteriorly based. **C.** Coronal exposure to access frontal bone and sinus. Care is taken to avoid traction

injury to the supratrochlear and supraorbital neurovascular bundles. **D.** Frontal craniotomy performed with exposed dura.

■ Repair and Closure

- If the anterior table is intact, accurate ostomy and identification of the boundaries of the frontal sinus are paramount.
 - Techniques described include using bayonet forceps, transillumination, and intraoperative navigation or 5-foot Caldwell x-ray with coin reference.⁵
- After outlining the borders of the sinus, 1.5-mm plates are preapplied, spanning the margins prior to osteotomy allowing for accurate repositioning of the anterior table.
- The anterior table is then perforated with a sagittal saw or side-cutting bur; the hand piece should be angled at 45 degrees toward the sinus and away from the cranial vault to avoid violation of the posterior table.⁵
- There is often extensive fracturing of the anterior table. In these cases, label the frontal bone fragments before removing them to facilitate their reassembly and store them in moist gauze.
- Once the frontal sinus is exposed, the opening to the frontal nasal duct is inspected and the patency assessed by passing a 10- or 12-French red rubber tube for a distance of 7 to 10 cm (**TECH FIG 2A**).
- If the patency of the duct cannot be ensured, and the posterior table is also involved, remove the posterior wall and repair lacerations of the dura. This is usually performed by the neurosurgery team.^{1,2,4}
- Strip the frontal sinus mucosa completely and supplement by burring the irregularities on the internal bony surfaces of the frontal sinus (**TECH FIG 2B**).^{1,2,4,5}
- A cuff of mucosa at the most cranial end of the frontonasal duct is preserved and dissected free from the bony canal.
 - A purse-string suture of this mucosal cuff is placed to effectively seal off the frontal nasal duct. We suggest using 3-0 polyglactin on a small tapered needle.

TECH FIG 2 • A. With the dura retracted, the extent of the frontal sinus injury can be assessed. **B.** An egg-shaped bur is used to remove the mucosa of the frontal sinus. **C.** Split-thickness calvarial bone graft is used to reconstruct the floor of the anterior cranial fossa. Drill holes are made to allow fixation with absorbable 2-0 monofilament sutures. **D.** The split-thickness calvarial bone graft is secured in place to

reconstruct the floor of the anterior cranial fossa, forming a right angle joint posterior to the frontal bar. **E.** Split-thickness calvarial bone graft reconstructing the floor of the anterior cranial fossa after suture fixation. **F.** Elevation of pericranial flap from the deep surface of the coronal flap using a no. 15 scalpel. **G.** Elevating the pericranial flap. **H.** Completion of scalp closure.

- Pack particulate cortical-cancellous bone grafts above this closure to further re-enforce the separation. Any defect of the frontal sinus floor is reconstructed with split-thickness cranial bone grafts.
 - Two small holes are drilled on the posterior edge of the bone graft with a 3-0 PDS placed through them as a loop. These loops will provide a posterior anchor to the pericranial flap.
 - The posterior wall of the frontal sinus is completely removed, creating a smooth continuous floor of the anterior cranial fossa (**TECH FIG 2C–E**).
 - Introduce the pericranial flap into the intracranial space, lining the floor of the anterior cranial fossa. Secure the posterior extent of the pericranial flap with a 3-0 PDS loop on the posterior edge of the bone graft on the floor.
 - A 4 mm horizontal slot is made in the frontal bone to accommodate the base of the pericranial flap.
 - After inseting the flap, access to the orbital rims or the orbits themselves will be impossible. It is therefore critically important that all the work in the orbits and supraorbital rims is complete prior to inseting the pericranial flap (**TECH FIG 2F**).
 - Reassemble frontal bone fragments with care taken to remove all the mucosal tissue. The frontal craniotomy is then repaired using 3-0 PDS, plates, and screws as needed.
 - Close the deep dermis using 3-0 polyglactin and the scalp with suture or staples.
 - Drains are used in some cases, with care taken to assure that unimpeded removal can occur (**TECH FIG 2G,H**).
-
-

PEARLS AND PITFALLS

Physical findings

- Search for and document any CSF leak or entrapment of mucosa within the intracranial space.^{1,2,4,5}
- Carefully examine for concomitant injuries and identify any numbness or paresthesia of the forehead indicating possible supraorbital and supratrochlear nerve injuries.
- Supraorbital foramen marks the lateral extent of frontal sinus.

Technique

- Bevel the incision to ensure that it travels parallel to the hair follicles to avoid alopecia.
- Once the level of the temporal line is reached, dissection should be carried deep to the superficial layer of the deep fascia to avoid transection of the temporal-zygomatic branch of the facial nerve.⁴
- Avoid raising the temporal fat pad, which devascularizes the fat pad leading to temporal wasting.⁵
- It is easier to dissect in the suprapericranial plane, leaving the pericranium on bone and then raising it as a separate layer in a second step.
- Remove all mucosa to avoid the formation of a mucocele.
- Watertight dural repair is of principal importance to help avoid CSF leaks and ascending infections from sinus spaces.
- Sufficient space between the frontal bone and supraorbital bar must be present to allow the pericranial flap to enter the intracranial space.

Postoperative

- Have a high index of suspicion to identify complications such as meningitis, mucocele, or mucopyocele leading to osteomyelitis.

POSTOPERATIVE CARE

- Immediate postoperative care should include evaluations of the neurological, visual, and olfactory systems.
- Patients should avoid nose blowing for at least 4 weeks following frontal sinus surgery.
- No aspirin for a week and avoid NSAIDs.
- Some surgeons may advocate steroid use for severe orbital trauma to help with postoperative edema; however, this must be balanced with the risk of complications related to perioperative steroids.

- Postoperative CT is recommended to assess complex fracture reductions.
- The scalp can be washed by postoperative day 5.
- Clinical follow-up should include counseling about signs and symptoms of complications, and patients should understand that these complications might occur years after the original trauma.^{1,6,7}

OUTCOMES

- Overall, cranialization has a very high success rate at preventing complications in both the short and long term after severe traumatic frontal sinus fractures and frontonasal duct disruption.
- One study of 72 patients with frontal sinus fractures reports a 6% mucocele rate. However, of the 30 patients who were treated with cranialization, none developed a mucocele.⁹ This prevention also helps avoid complications of mucopyocele, meningitis, and osteomyelitis.
- Overall, long-term studies after frontal sinus fractures are lacking because patients tend to have poor follow-up unless complications arise. Conservative observation has also been advocated in specific instances of limited CSF leak or when endoscopic measures can be used to temporize or relieve frontonasal obstructions.^{6,7,10}

COMPLICATIONS

- If all mucosal lining is not removed, the patient is at risk of developing a mucocele, which may progress to a mucopyocele and frontal bone osteomyelitis (a condition known as Pott puffy tumor) and subsequent brain abscess.^{2,3}
- A CSF leak may occur with unrecognized or incompletely repaired dural injuries.
 - Manage this injury with packing, bed rest, lumbar drain, endoscopic endonasal management, and revision surgery.
- Meningitis

FIG 4 • Intermediate postoperative photo showing the frontonasal region.

- Injury to the temporal-zygomatic branch of the facial nerve leading to ipsilateral forehead paralysis
- Hollowing of the temporal region secondary to excessive disruption of the temporal fat pad
- Widened scar from the coronal incision
- Chronic/severe frontal pain (**FIG 4**)

49 Frontal Sinus Obliteration with Fat

CHAPTER

Matthew M. Smith and Alessandro de Alarcon

DEFINITION

- Obliteration of the frontal sinus is the process of replacing a diseased frontal sinus that is normally air-filled.
- The diseased frontal sinus is obliterated with another material, such as fat.

ANATOMY

- The midface is made up of five paired paranasal sinuses (maxillary, anterior ethmoid, posterior ethmoid, sphenoid, and frontal)
- The boundaries of the frontal sinus are as follows:
 - Anterior: Anterior wall of the frontal sinus
 - Posterior: Posterior wall of the frontal sinus and anterior cranial fossa
 - Inferior: Orbit
- The anterior wall of the frontal sinus is significantly thicker than the posterior wall.
- The frontal sinus is the last paranasal sinus to develop and usually begins to pneumatize around 6 years of age (**FIG 1**).
- It is innervated by the supraorbital and supratrochlear nerves, which are branches of the first branch of the trigeminal nerve (V1).

FIG 1 • Growth of the frontal sinus.

- The frontal sinus drains into the middle meatus via the hourglass-shaped frontal sinus outflow tract. The boundaries of the frontal sinus outflow tract are as follows:
 - Anterior: Nasofrontal bar, agger nasi cell
 - Posteroinferior: Ethmoid bulla
 - Posterosuperior: Anterior cranial fossa
 - Medial: Middle turbinate
 - Lateral: Lamina papyracea

PATHOGENESIS

- Frontal sinus injury is the primary indication for frontal sinus obliteration.
 - Chronic frontal sinusitis secondary to obstruction of the frontal sinus outflow tract.
 - Prior frontal sinus surgery with subsequent mucocele formation.

- Frontal sinus malignancy with subsequent need for obliteration after resection of tumor.
- Direct forehead trauma with subsequent frontal sinus wall fractures.
 - Isolated anterior frontal sinus wall fractures with displacement and nondisplaced posterior wall frontal sinus fractures without CSF leak are the most amenable to frontal sinus obliteration.
 - Displacement of the posterior frontal sinus wall and/or CSF leak is more frequently treated with cranialization of the frontal sinus rather than obliteration.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history for each patient will be directed toward the proposed cause of his or her frontal sinus problem.
- For all patients, it is important to obtain history regarding changes in vision, mechanism of frontal sinus injury (chronic inflammatory, traumatic), nasal obstruction, persistent clear rhinorrhea, purulent rhinorrhea, fevers, headaches, swelling of the forehead, changes or lack of smell, prior sinus surgeries, and symptoms of meningitis.
- A complete visual examination should be performed, including visual acuity, visual fields, pupillary reflex, accommodation, and extraocular movements.
- Anterior rhinoscopy should be used to examine the nasal cavities for any evidence of trauma, CSF leak (clear rhinorrhea), or malignancy prior to frontal sinus surgical intervention.
- Nasal endoscopy is not needed to view the frontal sinus prior to surgery but is useful if the patient has had prior surgery and allows the frontal sinus outflow tract to be easily viewed with an angled endoscope (45 or 70 degree).
- If the patient has symptoms of persistent or intermittent clear rhinorrhea, the patient should be instructed to sit in a sniffing position for 3 minutes with a small basin or cup to collect the clear nasal drainage. This fluid can then be sent for examination of beta-2-transferrin for confirmation of CSF leak.
- For those patients with a history of traumatic frontal sinus fracture, the evaluation for potential foreign bodies within the frontal sinus and other craniofacial fractures should be completed.

IMAGING

- CT scan of the sinuses is paramount for the bony framework of the frontal sinuses.

- Axial, sagittal, and coronal views should all be obtained to fully view the frontal sinus in different planes (**FIG 2A,B**).
- 0.5-mm cuts should be obtained in order to detect small defects in the frontal sinus.
- 3D reconstruction of the frontal sinus can be obtained and is helpful, but not necessary.
- Historically a 6-foot Caldwell view with an AP x-ray of the head was obtained. A quarter was placed over the patient's forehead during the x-ray to create an image that could then be laid over the patient for an actual size of the frontal sinus.
- MRI with contrast should be obtained prior to surgery if violation of the posterior frontal wall is suspected to ensure there is no evidence of an encephalocele and to further evaluate the surrounding soft tissues (**FIG 2C**).

DIFFERENTIAL DIAGNOSIS

- Chronic frontal sinusitis
- Pott puffy tumor
- Frontal sinus mucocele
- Frontal sinus fracture
- Encephalocele
- Frontal sinus malignancy

NONOPERATIVE MANAGEMENT

- For nondisplaced fractures of the anterior frontal sinus, observation is an option, but with any type of mucosal disruption, the patient will be at risk for mucocele or mucopyocele.
- Endoscopic management of the frontal sinus may also be explored for chronic frontal sinusitis and is frequently used as first-line treatment.

SURGICAL MANAGEMENT

Preoperative Planning

- All imaging must be reviewed prior to surgery to obtain a proper road map of the frontal sinus.
 - Evaluate for presence of anterior and posterior table fractures.
 - Evaluate for possible anterior cranial fossa communication/involvement.
- If there is any concern for CSF leak, attempts should be made to collect clear

rhinorrhea for beta-2-transferrin examination.

- If enough fluid cannot be collected for examination, a gross evaluation of the fluid can be performed by placing a few drops of the drainage on a white sheet and looking for a “halo sign.”
- A collection of blood in the middle with a clear ring of surrounding fluid is indicative of CSF.
- Preoperative discussion with the patient and family regarding the extensive nature of the coronal incision should be performed.
- Antibiotics should be given prior to surgical intervention.
 - Cefazolin, clindamycin, and ampicillin-sulbactam are all appropriate choices.
 - If the patient has a history of MRSA, then vancomycin should be added to the antibiotic regimen.

Positioning

- Patients are placed supine on the operating room table.
- If a neurosurgical team is involved with the operation, then fixation in a Mayfield retractor will be used with removal of the headboard. Otherwise, the patient’s head is placed on a foam donut and positioned in a neutral position.

Approach

- The primary approach to open frontal sinus obliteration is through a coronal incision.
- Endoscopic approaches to the frontal sinus (first reported in 2005) are feasible but should only be considered in chronic frontal sinusitis.¹

FIG 2 • **A.** Coronal CT showing bone window. **B.** Sagittal CT showing bone window. **C.** Sagittal MRI T2 sequence.

TECHNIQUES

■ Open Coronal Approach to Frontal Sinus Obliteration

Preparation and Exposure

- The eyes are coated with optical lubricant and then either covered with a clear dressing or sutured together by performing a tarsorrhaphy with a 5-0 or 6-0 monofilament colored suture (preferably blue or green so as not to blend in with eyelashes).
- A small strip of hair is cut with clippers where the planned coronal incision is to be placed (**TECH FIG 1A**).
- A clear plastic drape can be placed over the upper lip to separate the oral cavity from the surgical field.
- Stereotactic navigation is then calibrated if used during the case.
- The face and scalp are prepped with iodine solution and draped with full view of the anterior scalp, forehead, and upper face (including eyes and nose).
- The abdomen is then prepped over the periumbilical area for fat harvest and draped with blue towels.
 - This area is covered with surgical drapes and marked for the subsequent abdominal fat harvest. The surgical drapes can be cut with scissors for access to the already prepped abdomen.
- A coronal incision is made from temporal line to temporal line, just anterior to the helical crus.
 - For improved appearance, the incision line is hidden within the hair line and may be staggered in a saw-toothed fashion.
- The incision is taken down to the periosteum exposing the frontal bone completely.
- Using the stereotactic navigation, the frontal sinus is then outlined for the proposed bony incisions.
- The periosteum of the frontal bone is elevated with a Freer elevator over the planned incision, leaving it pedicled anteroinferiorly over the brow line (**TECH FIG 1B**).

TECH FIG 1 • A. Planned sawtooth coronal incision with hair removed from suture line. **B.** Purple marker outlines planned osteoplastic flap. The periosteal flap has been elevated and is pedicled anteroinferiorly and is retracted with hook retractors.

- The frontal osteoplastic bone flap is then created using a reciprocating or oscillating saw over the previously planned outline of the frontal sinus.
- A high-speed cutting drill may be used instead but can result in increased injury to the edges of the bone flap.
- If there was a previous fracture in the anterior table of the frontal sinus, then this can serve as one or all of the planned cuts into the frontal sinus.
- After the circumferential cuts are made, the only piece of bone that should be left attached is the frontal intersinus septum, which is removed with a reciprocating saw, an oscillating saw, a drill using a round drill bit, or an osteotome.
- The frontal osteoplastic flap is then wrapped in saline-soaked gauze and placed on the back table for later use.

Obliteration of the Sinus with Fat

- If an infectious etiology has been identified, cultures are obtained immediately upon entry to the sinus.

- The frontal sinus lining mucosa is then completely removed using forceps.
- A high-speed drill with a diamond bur is then used to smooth the inner edges of the sinus to remove all microscopic areas of mucosa. This is also used to smooth any bony spicules or ledges.
 - We recommend using loupe magnification or the assistance of angled endoscopes to ensure that all of the mucosa is removed and bony edges are smooth.
 - If there is evidence of a nondisplaced frontal sinus fracture, extreme care is taken during removal of the mucosal lining of the posterior frontal sinus wall to prevent displacement of the fracture.
- Abdominal fat is then harvested for obliteration of the frontal sinus.
 - A no. 15 blade is used to make a periumbilical incision.
 - Blunt dissection with a hemostat is used to elevate the area and expose the proposed fat graft.
 - Fat is then harvested en bloc for obliteration of the frontal sinus. The total amount of fat is dependent on the volume of the frontal sinuses to be obliterated.
 - The incision is then closed in sequential fashion, and dressing is placed over the abdominal incision.
- A 1 × 1 cm piece of temporalis muscle is then harvested for obliteration of the frontal sinus outflow tract.
- The frontal sinus outflow tracts are then identified and plugged with the previously harvested temporalis muscle.
- The previously harvested fat is then used to fill and obliterate the frontal sinuses.

Plating and Completion

- The osteoplastic bone flap is replaced and secured with titanium or absorbable plates. If the frontal bar was removed or required reconstruction, it is replaced prior to plating the osteoplastic bone flap (**TECH FIG 2**).
- The periosteal flap is then laid over the bony flap and sutured to the surrounding periosteum with 3-0 suture.
- The wound is irrigated with saline and hemostasis is achieved with electrocautery.

TECH FIG 2 • Frontal bar is being reconstructed with an absorbable plating system. After plating the frontal bar, the osteoplastic bone flap is replaced and secured.

- Negative pressure drains are placed to collect blood or serous fluid collections.
- The incision is closed in multiple layers, with sutures or staples to close the skin.
- Antibiotic ointment is then applied to the incision, and the head is wrapped in a compressive dressing.

PEARLS AND PITFALLS

- | | |
|-------------------|---|
| Hemostasis | ■ Obtain hemostasis prior to closure. Negative pressure drains allow monitoring of postoperative fluid in this area. We recommend less than 30 mL of drainage in a 24-hour period and avoidance of any bending, Valsalva maneuvers, nose blowing, or excessive activity for 2 wk postoperatively. |
| Technique | ■ All mucosa must be removed from the frontal sinus to prevent subsequent mucocele formation. This can be ensured with drilling |

and smoothing of the frontal sinus bone.

POSTOPERATIVE CARE

- Patients should be placed on postoperative antibiotics for at least 14 days, usually amoxicillin-clavulanate.
 - If there is concern for meningitis or other complicated infectious etiology, the type and course of antibiotic should be tailored to the individual patient.
- For external incisions, antibiotic ointment should be used to coat the area to promote healing.
- Compressive head dressings can be removed in 48 to 72 hours.
- Negative pressure drains are kept in place until the output for each drain is less than 30 mL of fluid over a 24-hour period.
- Avoid bending, Valsalva maneuvers, nose blowing, or excessive activity for 2 weeks to prevent bleeding.
 - Patients should be instructed to “open-mouth sneeze” to avoid excessive nasal airflow pressure.
- Nasal saline rinses are recommended to prevent nasal crusting if endonasal surgery was performed.
- Staples or sutures in the scalp should be removed in approximately 10 days.
- Postoperative CT and/or MRI should be performed to establish a baseline of the newly obliterated frontal sinus.

OUTCOMES

- Greater than 90% success rate of frontal sinus obliteration has been reported.²

COMPLICATIONS

- Mucocoeles or mucopyocoeles may occur years later if any mucosa is retained in the frontal sinuses.
 - Weber et al. performed a long-term follow-up MRI study that detected mucocoeles in almost 10% of patients after frontal sinus injury.³
- CSF leak is a potential risk with any damage to the posterior frontal sinus wall and subsequent dural injury during surgery.
- Meningitis may occur through communication with the anterior cranial fossa if there is a defect in the posterior frontal sinus wall.

50 Pericranial Flap Harvest for Frontal Sinus Obliteration

CHAPTER

Mahmoud Hassouba and John A. van Aalst

DEFINITION

- The pericranial flap is a well-vascularized, versatile cranial periosteal flap that can be based anteriorly on the supratrochlear and supraorbital arteries or laterally on the superficial temporal artery.¹
- The pericranial flap is most commonly used for reconstruction of anterior skull base defects, including obliteration of the drainage system of the front sinus following frontal sinus fracture.

ANATOMY

- The scalp consists of five layers: skin, subcutaneous connective tissue, galea aponeurotica, loose areolar tissue, and the pericranium.
- The pericranium is the periosteum of the skull bones and is continuous with the endosteum along the cranial suture lines.
- The pericranial flap consists of the skull periosteum with the overlying subgaleal areolar tissue.
- The blood supply of the anteriorly based pericranial flap is derived from the deep branches of the supraorbital and supratrochlear arteries, and both are branches of the ophthalmic artery.
- The deep branches arise from the supratrochlear and supraorbital artery exiting at the level of the supraorbital rim.²
- There is wide variation in the size of these arterial branches depending on the size of the frontal branch of the superficial temporal artery.²
- The axial length of these branches ranges between 15 and 60 mm and most commonly is approximately 40 mm in length.²
- In the horizontal plane, the anastomosis between the deep branches is not well

developed, and except for the glabellar region, no anastomoses cross the midline.

PATHOGENESIS

- The most common indication for sinus obliteration requiring pericranial flap is a fracture of the posterior wall of the frontal sinus.
- As with most craniofacial injuries, frontal sinus fractures result from high-velocity blunt trauma such as motor vehicle accidents.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Frontal sinus fractures are often associated with other facial injuries that require a detailed history, including the mechanism of trauma, as well as a thorough general and craniofacial-centric physical examination.
- History taking may be complicated due to patient head injury with loss of consciousness.
- The main presenting symptoms are forehead swelling with or without skin lacerations, forehead paresthesia, and forehead and nasal pain.
- Signs of frontal sinus fractures include forehead tenderness, contour deformity, crepitus, and cerebrospinal fluid (CSF) rhinorrhea.
- Displaced fractures without skin lacerations may be masked by the overlying soft tissue swelling.
- All lacerations should be examined under aseptic conditions to evaluate the integrity of both the anterior and posterior tables as well as the dura.
- The nasal cavity should be examined for the presence of CSF drainage.

IMAGING

- CT scan of the facial bones with coronal and axial cuts is the standard for diagnosis of fractures involving the frontal sinus.
 - 3D reconstructions may be helpful in diagnosing associated craniofacial injuries.

SURGICAL MANAGEMENT

- Indications for frontal sinus obliteration include fractures of the floor or posterior wall of the sinus, oncologic or inflammatory lesions of the frontal sinus such as osteomas or osteomyelitis, vascular lesions such as arteriovenous malformations, and failure of endoscopic sinus drainage surgery.³

PREOPERATIVE PLANNING

- Routine preoperative lab results should be reviewed, and any abnormal finding should be corrected to prepare the patient for surgery.
- All available imaging should be available and displayed in the operating room.
- A sterilized radiographic template of the frontal sinus can be prepared from a Caldwell radiograph.
- Doppler ultrasound should be available in the operating room for intraoperative localization of the flap pedicle if distorted anatomy is anticipated.

Positioning

- The patient is placed in supine position on the operating room bed.
- Oral intubation is preferred with the tube placed centrally and inferiorly.

Approach

- If a forehead laceration already exists, it can be extended into a natural crease.
- A midforehead incision or a butterfly transglabellar incision may be used.⁴
- The coronal incision is the most reliable and aesthetically favorable approach for exposure of the forehead and facilitates harvest of the pericranial flap.
- The sex of the patient and location of the anterior hairline should be taken in consideration when choosing the location of the coronal incision
- In individuals with posteriorly displaced anterior hairline or patients with male pattern baldness, the incision can be placed as far posteriorly as the upper occiput.

TECHNIQUES

■ Anteriorly Based Pericranial Flap

- The coronal incision is made 2 to 3 cm posterior to the hairline and extends to the auricular helix on both sides (**TECH FIG 1A**).
- The flap is dissected anteriorly in the subperiosteal plane to the level of the supraorbital rim and may need to be extended to access other fractures of the craniofacial skeleton (**TECH FIG 1B**).
- Marking of the frontal sinus can be performed using the premade template.
- The frontal sinus is then accessed through a pre-existing anterior table

fracture or by removal of the frontal bone in conjunction with the neurosurgery team.

- Mucosal lining of the sinus is completely exenterated using a periosteal elevator; 0.5 to 1 mm of the osseous lining is then removed using a bur.
- At the ostia of the nasofrontal ducts, the mucosa is folded on itself.
- Doppler scanning may be used for accurate localization of the pericranial flap pedicle and aid in planning the flap.
- An anteriorly based periosteal flap is dissected from the coronal flap with a no. 15 blade in the subaponeurotic plane to the supraorbital rim (**TECH FIG 1C**).
- The flap is then folded against itself to fill and obliterate the frontal sinus, acting as a barrier between the brain and remaining sinus (**TECH FIG 1D**).
- The anterior table is then rigidly fixated in place leaving a 3- to 5-mm gap between its inferior border and the frontal bar to prevent compression of the blood supply to the flap (**TECH FIG 1E**).
- A suction drain is then placed in the subgaleal plane, and the coronal flap is redraped and the incision is closed in layers.

TECH FIG 1 • A. Placement of coronal incision. **B.** The coronal incision proceeds through the layers of the scalp to the subpericranial plane. (These layers can be remembered using the acronym SCALP.) Dissection is performed on the skull to the orbital rim and, as necessary, into the area of the orbits, exposing the zygomatic arches bilaterally. The pericranial flap is exposed and separated from the overlying soft tissue. **C.** Elevation of the pericranial flap from the coronal flap. Frontal sinus has been exposed by removal of anterior table of frontal sinus. **D.** Obliteration of the frontal sinus and frontal recess by folding pericranial flap onto itself and filling the frontal sinus. This serves as a barrier between the brain and remnant sinus cavity. **E.** Before the frontal bone (*asterisk*) is replaced, the anterior region of craniotomy is burred to ensure that the edges are smooth and do not impinge on the pericranial flap as it enters the intracranial cavity (*arrows*). The bone flap is then secured, and the skin is closed.

■ Laterally Based Pericranial Flap

- All operative steps are similar to harvest of the anteriorly based flap, with the exception that the flap is either harvested unilaterally with its base in the

temporal area with blood supply from the superficial temporal artery or bilaterally depending on the size of the sinus.

- The base of the flap is located approximately 2 cm from the gap between the temporoparietal fascia and the galea aponeurotica.
- The width of the flap base usually varies between 5 and 8 cm depending on the size of the frontal sinus.
- A unilateral flap should not extend beyond the midline.
- The dimensions of the flap may vary but can be up to 10 × 10 cm according to the tissue amount required to fill the frontal sinus.

PEARLS AND PITFALLS

Coronal incision	■ Zigzag or curved incision is made to facilitate accurate closure at the end of the procedure.
Dissection	■ Care should be taken while dissecting the flap medially to avoid injury to the deep branches of the supratrochlear and supraorbital artery and laterally to avoid injury to the frontal branch of the facial nerve.
Dura	■ If the dura is exposed, it should be carefully examined and fenestrations should be repaired.
Hemostasis	■ Careful hemostasis should be achieved before closure of the coronal flap to avoid hematoma formation that can lead to flap compression and necrosis.

POSTOPERATIVE CARE

- The patient will require monitoring in the ICU because of the high likelihood of head injury associated with frontal sinus injury.
- Head of bed elevated to 45 degrees to help venous drainage and avoid soft tissue swelling.
- Perioperative antibiotics are indicated because of intracranial extension for 7 to 10 days.
- Drain remains in place until output is less than 30 mL for 24 hours.
- Narcotic pain medications are preferred during the first week after the procedure and are titrated to the patient's level of pain.

OUTCOMES

- Successful outcomes of obliteration of the frontal sinus depend on multiple factors, mainly total removal of mucosal lining and complete obliteration of the sinus.
- Aesthetic outcomes of forehead contour after surgery are usually satisfactory.
- Most published series in the literature report 100% patient satisfaction with the aesthetic and functional outcomes after frontal sinus obliteration using pericranial flaps.^{1,4-7}

COMPLICATIONS

- Early
 - Sinus obliteration using pericranial flaps is associated with low rates of complication.
 - Seroma formation: Can be avoided by drain placement
 - Active bleeding leading to expanding hematoma requiring flap exploration
 - Place a postoperative drain.
 - Early recognition of the hematoma and re-exploration.
- Late
 - Persistent headaches
 - Forehead contour deformities
 - Sinus infection: requires admission, IV antibiotics, and possible surgical debridement
 - Inadequate mucosal removal leading to mucocele formation; may present more than a decade after sinus obliteration.¹

51 Endoscopic Correction of Frontal Sinus Fractures

CHAPTER

Patrick M. Colley, Kibwei A. McKinney, and Brent A. Senior

DEFINITION

- Frontal sinus fractures involve the anterior or posterior table of the frontal bone.
- Displacement in frontal sinus fractures is classified as one width of the anterior or posterior table.

ANATOMY

- The frontal bone has both vertical and horizontal components.
 - The vertical component is the bone of the forehead and is composed of the anterior and posterior tables.
 - The horizontal component makes up the superior orbital roof and floor of the frontal sinus.
- The vertical portion of the frontal bone contains a pneumatized frontal sinus in greater than 90% of the population.
- The frontal sinus begins its development at 4 years of age and continues to develop until the late teenage years.
- The anterior table of the frontal sinus is a bicortical structure made of cancellous bone that begins at the nasofrontal suture line inferiorly and averages 4 to 12 mm in thickness.
- The posterior table of the frontal sinus is thinner than the anterior table, with an average thickness of 0.1 to 4 mm. Its inner cortex is closely adherent to the underlying dura.
- The anterior and posterior tables of the frontal sinus converge inferiorly to form the frontal recess or frontal sinus drainage pathway (FSDP), where the frontal sinus drains into the middle meatus or ethmoid infundibulum,

depending on where the uncinate process inserts superiorly (**FIG 1A,B**).

- At the superior-most portion of the FSDP is the frontal recess, a three-dimensional (3D) structure with the following boundaries:
 - Anterior—the agger nasi cell and/or the uncinate process
 - Posterior—the anterior wall of the ethmoid bulla and any suprabullar ethmoid cells
 - Lateral—lamina papyracea of the orbit
 - Medial—the lateral lamellae of the skull base and attachment of the middle turbinate to the skull base
- The soft tissue overlying the frontal bone consists of skin, subcutaneous soft tissue, frontalis muscle, and pericranium.
- At the glabella and medial portion of the supraorbital rim, the soft tissue is thicker than it is at the superior portion of the forehead due to the presence of the orbicularis oculi, procerus, and corrugator muscles.

FIG 1 • A. Sagittal drawing of the frontal sinus drainage pathway (FSDP). The pathway passes posterior to the agger nasi cell and anterior to the ethmoid bulla before draining into the middle meatus. **B.** Coronal drawing showing the most common relationship of the FSDP to the lamina papyracea and middle turbinate. **C.** Anterior view of the face showing the location of the supratrochlear and supraorbital neurovascular bundles. The supratrochlear bundle can be located approximately 1.5 cm from midline, while the supraorbital exits its foramen approximately 2.5 cm from midline. CSM, corrugator supercilii muscle; PrM, procerus muscle; StN, supratrochlear nerve; StA, supratrochlear artery; StV, supratrochlear vein; SoN; supraorbital nerve; SoA, supraorbital artery; SoV, supraorbital vein; FrM, frontalis muscle. **D.** Endoscopic view of the supratrochlear and supraorbital bundles. StN, supratrochlear nerve; SoN, supraorbital nerve; DSM, depressor supercilii muscle; CSM, corrugator supercilii muscle; Ant. Table, anterior table of the frontal sinus. External palpation can aid in orientation while

dissecting inferiorly and alert the surgeon when the supraorbital rim is near.

- The subpericranial plane constitutes a bloodless space and provides access to the underlying anterior table of the frontal sinus.
- The supraorbital and supratrochlear nerves supply sensation to the forehead skin and course from the superior orbital rim, inferiorly, to the vertex of the scalp, superiorly (**FIG 1C,D**).
- The supraorbital nerve, the more lateral of these two structures, is a branch of V1 that passes through the supraorbital foramen and travels deep to the corrugator muscles, before penetrating the frontalis muscle and traveling within the subcutaneous tissue in its superior course.
- The supratrochlear nerve passes just above the superior oblique muscle and its trochlea before coursing in a similar plane to the supraorbital nerve superiorly along with the supratrochlear artery.
- Injury to these nerves via trauma or surgical incision leads to a loss of sensation superior to the site of injury.

PATHOGENESIS

- The frontal bone is one of the stronger bones in the human body, and fracturing it requires a pressure of 800 to 1600 ft-lb. However, an aerated frontal sinus reduces the ability of the frontal bone to withstand pressure, thus making pneumatized areas more susceptible to fractures than other regions of the frontal bone.
- The most common mechanisms of injury resulting in frontal sinus fracture are motor vehicle collision (42%), assaults (14%), motorcycle collisions (10%), pedestrians struck by motor vehicles (8%), and ballistic injuries (7%).¹
- The most common type of fracture is a combined fracture involving the anterior and posterior tables as well as the FSDP, occurring between 55% and 67% of the time. Isolated anterior table fractures are seen in 33% of frontal sinus fractures, with isolated posterior table fractures making up less than 5%.¹

NATURAL HISTORY

- Injury to the frontal sinus can lead to complications from cerebrospinal fluid (CSF) rhinorrhea, damage to the FSDP, or changes in the aesthetic structure of the facial skeleton.
- The posterior table of the frontal sinus is thin and adherent to the underlying

dura, making a tear and subsequent CSF leak more likely when the posterior table has been significantly injured or displaced.

- The FSDP is the only pathway of egress for mucus produced by the frontal sinus mucosa. Obstruction of this space can lead to chronic sinus disease and frontal mucocele formation.
- The frontal bone supplies the height and contour of the entire forehead. Fractures of the frontal bone as small as 2 to 3 mm can lead to significant alteration in the appearance of the forehead, particularly in the superior portion, where the overlying soft tissue is thinner.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history obtained from a patient with a suspected frontal sinus fracture should focus on the method of injury, neurologic complaints, visual changes, and the possibility of a CSF leak.
 - Because of the large amount of force required to produce a frontal sinus fracture, loss of consciousness is associated with over 70% of these injuries, while intracranial injuries are seen in 39%.²
 - Ophthalmologic injuries can be seen in 26% of frontal sinus fractures.²
- The physical examination in patients suspected of having a frontal sinus fracture involves a complete trauma assessment and typically requires consultation with otolaryngology, plastic surgery, neurosurgery, and ophthalmology.
- A thorough head and neck examination should be conducted including assessment of the airway and the neck, prior to focusing on maxillofacial injuries.
- Examination of the entire maxillofacial skeleton should be conducted, as 87% of patients with a frontal sinus fracture have other maxillofacial injuries.³
 - The forehead should be examined for abnormalities in contour, tenderness, crepitus, and paresthesias.
 - Lacerations should be examined under sterile conditions and probed carefully until the integrity of the underlying frontal bone can be assessed on imaging.
 - The orbital rims and integrity of the medial canthal tendon (MCT) can be assessed with palpation and by placing a thumb and index finger over the nasal root and carefully applying lateral tension on each lower lid. Minimal movement of 2 to 3 mm with a defined endpoint is normal, while excessive movement or orbital movement means that the integrity of the MCT has been compromised.

- MCT injuries are often seen with naso-orbital-ethmoid fractures
- CSF leaks should be suspected in all patients with frontal sinus fractures.
 - The nasal cavity should be cleared of debris and examined using nasal endoscopy
 - Any rhinorrhea should be examined using the halo test or sent for beta-2-transferrin analysis.^{1,3-6}
 - The halo test consists of capturing fluid from the nasal secretions on a cloth or gauze and observing whether a clear “halo” is visible around a central pool of blood within the drainage (CSF migrates faster than does blood). This test is suggestive of the presence of CSF but is not diagnostic as saline and mucus can also lead to false-positive results.
 - Testing of fluid for beta-2-transferrin is the mainstay of evaluation for CSF. This protein can be found in CSF, vitreous humor of the eye, and perilymph.

IMAGING

- Fine-cut, triplanar maxillofacial CT scans are the standard means of radiologic evaluation for frontal sinus fractures.
 - Coronal views provide excellent visualization of the frontal sinus floor, anterior ethmoid cells, and medial orbital walls. Injuries to any of these areas mean there is a high likelihood of damage to the FSDP and an increased risk of chronic sinusitis and mucocele formation.
 - Axial views are used to evaluate displacement of frontal sinus fractures and can demonstrate comminution or pneumocephalus (**FIG 2**).
 - The patency of the FSDP is best assessed on the sagittal views, though it requires careful assessment in all planes.
 - Fractures involving the FSDP typically occur with more severe maxillofacial trauma, and patients are 3 times more likely to have other facial fractures when this area is involved.¹
- 3D reconstruction is useful in minimally displaced fractures of the anterior table and can help determine if expectant management is an acceptable treatment option.

FIG 2 • An axial CT view of a minimally displaced frontal sinus fracture. The posterior table appears intact, and the frontal sinus is completely opacified.

- If expectant management with delayed endoscopic treatment is a possible treatment option, the axial views provide the most accurate means of estimating the size of the fracture, as they are not influenced by volume averaging.

NONOPERATIVE MANAGEMENT

- Based on the algorithm in **FIG 3**, expectant management of a frontal sinus fracture can be considered if no significant posterior table injury is present.
- Repeat imaging and physical examination should be conducted regularly at 3, 6, and 12 months on all patients who are observed after this injury.
- The frontal sinus mucosa normally regains proper mucociliary clearance spontaneously after a fracture. However, repeat imaging is required to confirm that the mucociliary clearance is functioning properly.
 - Patients can suffer from chronic frontal sinusitis or possibly mucocele formation if the mucosa does not function properly.
- Observation is an appropriate treatment option in patients with no evidence of FSDP injury who have nondisplaced fractures or fractures limited to either the anterior or posterior table.
- Isolated posterior table fractures can be observed once FSDP injury, dural tear,

and CSF leak have been ruled out. Mucocoele formation due to ingrowth of mucosa into the fracture is rare but should be evaluated at regular intervals.

- Minimally displaced anterior table fractures without FSDP injury can be observed with close follow-up. Should the patient have aesthetic deformities after resolution of the soft tissue edema, endoscopic cranioplasty can be a useful means of correcting this issue.
- These patients often have minimal cosmetic deformity 3 to 6 months after their injury, particularly those with thick brows.

SURGICAL MANAGEMENT

- In the acute setting, endoscopic reduction and internal fixation of anterior table fractures is a treatment option when there is a minimally displaced, isolated, noncomminuted anterior table fracture that does not involve the FSDP.

FIG 3 • Algorithm for the management of anterior table fractures. Endoscopic or expectant management can be considered in four of the eight clinical scenarios. Posterior table injury includes displacement of more than one table width, evidence of intracranial injury, a comminuted fracture, or a cerebrospinal fluid leak. FSDP, frontal sinus drainage pathway.

- Minimally displaced fractures are typically defined as less than 2 mm or 1 width of the anterior table.

- The patient with a receding hairline may not be an optimal candidate for this approach, as some endoscopic incisions are highly visible.
- Delayed endoscopic cranioplasty is indicated in the patient who was initially observed after sustaining a minimally displaced anterior table fracture without FSDP injury but has continued cosmetic deformity of the frontal area following resolution of the soft tissue edema.
- Discussion of traditional open surgical techniques for correcting frontal sinus fractures can be found in other chapters.
- Endoscopic management of these fractures can avoid a large coronal incision and allow for a quicker recovery.
- Endoscopic cranioplasty and fixation techniques should be performed by surgeons who are proficient in endoscopic browplasty procedures.
- Additional endoscopic endonasal sinus procedures required for the involved frontal sinus can accompany delayed treatment of the fracture.⁷
- Endoscopic frontal sinusotomy can be performed to improve aeration of the frontal sinus and can also be used to provide access for balloon catheterization of the frontal sinus.
- Transnasal endoscopic placement of a frontal sinus instrument or Foley catheter balloon into the frontal sinus can be used to reduce an anterior table fracture and provide the support required to place a screw into the fractured segment of bone.

Preoperative Planning

- CT imaging should be reviewed prior to the procedure.
- Proper antibiotic coverage should be started prior to the procedure.
 - Adequate coverage of typical sinus flora is provided by using ampicillin-sulbactam or clindamycin.
- Discussion with the patient regarding the possible need for conversion to an open procedure including the use of a coronal incision should be included in the consent prior to the procedure.
- The proper equipment should be present in the operating room, including 4 mm 30- and 70-degree endoscopes (**FIG 4**), a rigid endosheath, a camera, standard endoscopic browplasty instruments, endoscopic video tower, and either a plating system or a porous polyethylene sheet depending on the type of planned repair.
- Preoperative measurement of the fracture and trimming of the polyethylene

sheet (0.85 mm thick) or mesh to dimensions 10 mm larger than the fracture size is recommended. This allows for overlap of the sheet over the defect edges and an area for screw placement.

- Hydroxyapatite cement can also be used for endoscopic treatment of frontal sinus fractures and provides similar cosmetic results.
- Caution should be exercised when considering hydroxyapatite cement, as it typically fills a portion of the underlying frontal sinus and can increase the risk of mucocele formation after this procedure.

FIG 4 • A 4-mm endoscope with an endoscopic sheath should be used once an optical cavity is created in a subperichondrial plane.

Positioning

- The patient should be positioned supine on the operating table, and the head of the bed should be turned between 90 and 180 degrees for complete access to the patient's head and placement of the endoscopic equipment and tower.
- The surgeon should sit at the head of the bed, facing toward the patient's feet. The endoscopic video screen should be placed near the abdomen, facing toward the head of the bed (**FIG 5**).
- The patient's eyes should be closed and protected to prevent accidental trauma during the procedure.
- Sterile prep is applied from the upper nose to an area at least 2 or 3 cm posterior to the hairline.

Approach

- The endoscopic approach is the same for both delayed and acute scenarios.

- The entire anterior table to the level of the superior orbital rims, inferiorly, and the temporal lines, laterally, can be accessed through two or three small incisions just behind the hairline.

FIG 5 • The surgeon should be seated at the head of the bed facing the patient with the screen at the level of the patient's abdomen.

TECHNIQUES

■ Endoscopic Approach to the Anterior Table of the Frontal Sinus

- Two parallel incisions should be marked on the forehead, approximately 2 cm behind the hairline (**TECH FIG 1**).
 - The central incision should be made in the midline and is used for the endoscope.
 - The lateral incision should be made 4 to 6 cm lateral to midline, on the side corresponding to the larger portion of the fracture.
 - Another vertical incision can be made on the contralateral side, if greater

reach is required in that area.

- If a large piece of porous polyethylene or mesh is to be used, the scalp incisions may need to be enlarged, or a temporal incision 2 cm behind the hairline should be made to introduce this material.

TECH FIG 1 • Incisions for endoscopic repair of frontal sinus fractures. A midline incision is separated from two lateral incisions by approximately 2.5 cm and placed 1 cm posterior to the hairline. The optional temporal incisions are even further lateral and should be made just posterior to the temporal hairline.

- The use of temporal incisions creates greater tissue trauma, introduces the possibility of injury to the frontal branch of the facial nerve, and does not increase the size of the optical cavity. This incision should be used with caution.
- Incisions should be made with a scalpel through the skin and subcutaneous tissue.
- Electrocautery can be used to continue the dissection to the subperiosteal layer.

- Cautery should be used sparingly on the subcutaneous tissue and skin to avoid damage to the hair follicles and subsequent alopecia.
 - Blunt dissection using a sharp dissecting instrument, such as the endoscopic periosteal elevator, should be used to create a pocket in the subperiosteal plane.
 - Bimanual palpation should be used to confirm that the pocket extends from both temporal lines to approximately 2 to 3 cm anterior to the incisions.
 - Blind dissection of this pocket is required before placement of the endoscope into the incision.
 - Introduce the 30-degree endoscope through the central incision and the dissecting instrument through the lateral incision and continue the dissection in the subperiosteal plane to a level just below the inferior edge of the fracture.
 - Ensure that the fractured segments are not displaced during this portion of the dissection, as they can be very difficult to move back into the proper orientation using the endoscope.
 - Alternatively, comminuted fracture segments can be removed and plated together on the back table if they are displaced.
 - Dissection over the fracture segment can also be performed in the suprapericranial layer by making a small incision in the pericranium and identifying the proper plane.
 - This technique allows the fracture segments to remain attached and reduces the likelihood of displacement during the dissection.
-

■ Endoscopic Reduction and Internal Fixation of the Anterior Table

- A 25-gauge hypodermic needle is used to identify the proper areas for percutaneous port placement.
 - All fractured segments should have at least two points of fixation with larger pieces benefitting from three points.
 - Ideally, one port incision could be used to place screws into multiple plates in order to decrease the number of incisions.
- A no. 11 blade scalpel should be used to create a stab incision in this area for placement of screws and other percutaneous instruments.
- Once the fracture is dissected free from the overlying periosteum,

instruments including nerve hooks and Steinmann pins should be introduced through the percutaneous ports to reduce the fracture segments.

- Miniplates can be introduced through the scalp incisions and moved to positions overlying the fracture segment.
- 1.7-mm self-drilling screws (4 to 6 mm in length) can be used percutaneously to fixate the fracture segments to the stable bone.
 - A drill with a percutaneous drill guide can be used to create starting holes on the fracture segments if the screws are not taking hold.
- Acellular dermis or Vicryl mesh can be placed over the surface of the repair in the subperiosteal plane to provide further camouflage of any remaining contour abnormalities.
- The percutaneous port incisions can be closed with absorbable sutures or tissue adhesives.
- The access incisions should be closed with absorbable deep sutures and skin staples.

■ Endoscopic Placement of Mesh or Polyethylene Plate

- Complete the endoscopic approach to the anterior table of the frontal sinus as described above.
 - Ideally, one port incision can be used to place screws into opposing areas of the plate or mesh to decrease the number of incisions.
- A no. 11 blade scalpel should be used to create a stab incision in this area for placement of screws and other percutaneous instruments.
- The precut polyethylene plate or mesh is introduced into the optical cavity and moved into the proper position.
 - A mark should be placed on the superior portion of the plate to aid with orientation after the plate is placed into the optical cavity.
 - The entire fracture should be covered with a portion of the plate overlapping the surrounding stable bone.
- 1.7-mm self-drilling screws (4–6 mm in length) should be used through the percutaneous ports to secure the plate or mesh to the stable bone (**TECH FIG 2**).
 - All plates and mesh should have at least two points of fixation, with larger

pieces benefitting from three points.

- Screws should be placed at least 2 mm from the plate edge in order to avoid tearing.

TECH FIG 2 • Endoscopic view of a percutaneous screwdriver used to place screws in the reconstructive plate. The percutaneous incision should be made in an area that allows for access to the entire plate if possible to reduce cosmetic deformity.

- Acellular dermis or Vicryl mesh can be placed over the surface of the repair in the subperiosteal plane to provide further camouflage of any remaining contour abnormalities.
- The percutaneous port incisions can be closed with absorbable sutures or tissue adhesives.
- The access incisions should be closed with absorbable deep sutures and skin staples.

PEARLS AND PITFALLS

Indications	■ Frontal sinus fractures that involve the FSDP, surrounding maxillofacial bones, or are severely comminuted make poor endoscopic candidates. ■ Fractures that also involve the posterior table may be endoscopic candidates if they are observed first to ensure there is no CSF leak.
Consent	■ A discussion should take place with all patients regarding the need for a possible coronal incision and open reduction with internal fixation if the fractures are not amenable to the endoscopic approach.
Preoperative planning	■ Miniplates can be used for reduction and internal fixation in the acute setting. ■ Polyethylene plates or mesh should be used in the delayed setting and should be cut to appropriate size based on the axial cuts of the CT scan before the case.
Camouflage	■ A thin layer of Vicryl mesh or acellular dermis should be placed over the fracture after plating or fixation to camouflage further contour abnormalities.
Postoperative care	■ Patients should undergo routine physical and radiologic examinations 1, 3, and 6 mo after endoscopic treatment of their fracture no matter which type of surgery was used. ■ Osteomyelitis and mucocele formation occur infrequently but have better treatment outcomes when recognized early.

POSTOPERATIVE CARE

- A mildly compressive dressing is placed over the forehead immediately after surgery to prevent hematoma or seroma formation.
 - This can be removed after 48 hours.
- The patient should be warned to avoid activities that put him or her at risk for future trauma to the forehead.
- The patient can resume regular activities after approximately 2 weeks or after most of the swelling has resolved.
- The staples are removed 7 to 10 days after the surgery.
- The patient should still receive routine physical examinations and CT scans 1, 3, and 6 months after the surgery to monitor for osteomyelitis and mucocele formation.
 - Annual imaging should be obtained after this period.

OUTCOMES

- Endoscopic treatment of frontal sinus fractures has a similar success rate to open approaches in regard to cosmetic outcomes, with a lower rate of complications.^{1,5}
- A smaller subset of patients with less severe fractures qualify for endoscopic management that leads to an inherent decrease in complications.

COMPLICATIONS

- Complications from endoscopic repair of frontal sinus fractures are similar to those from open repair and include wound infections, osteomyelitis, mucocele, mucopyocele, aesthetic complications, paresthesias to the frontal area (secondary to injury of the supraorbital or supratrochlear neurovascular bundles), diplopia, hematoma or seroma formation, hardware infection, and bone resorption.^{1-6,8}
- Mucoceles can form at any point from the immediate postoperative period to 20 years after the surgery.

Operative Management of a Late Presentation of Frontal Sinus Mucocele

52

CHAPTER

Kibwei A. McKinney and Brent A. Senior

DEFINITION

- A mucocele is a benign, cystic collection of mucus lined with respiratory epithelium that results from obstruction of the drainage pathway of a paranasal sinus ostium.
- The mucus within a mucocele may become infected and is then termed a pyocele or mucopyocele.¹
- Mucoceles present most frequently in the frontal and ethmoid sinuses, accounting for between 54% and 73% of lesions occurring within the paranasal sinuses.²
- The vast majority of mucoceles occur in the setting of pre-existing sinus disease (eg, nasal polyps or sinonasal neoplasms), whereas a minority present as a long-term sequela of prior trauma to the frontal sinus drainage pathway.³
- Trauma to the frontal drainage pathway is thought to result in post-traumatic scar formation, inflammation, and obstruction that prevent normal mucociliary clearance, thus resulting in mucocele formation.^{4,5}
- Frontal mucoceles can result in significant morbidity, due to their expansile, erosive nature, and close proximity to the orbit and brain. Complications include facial asymmetry, orbital proptosis, cellulitis of the orbit and facial skin, and intracranial extension.⁶
- The treatment of mucoceles of the frontal sinus is particularly challenging due to the limitations of external and endoscopic techniques.
- External approaches may result in poor appearance, hypesthesia of the facial skin, and poor access to the frontal sinus drainage pathway.

- Endoscopic approaches have decreased morbidity but are limited in their ability to access lesions localized to the superior and lateral aspects of the sinus.

ANATOMY

Frontal Sinus

- The frontal sinuses are paired structures of the forehead that are present in 90% of the population and exhibit different patterns of pneumatization among individuals.⁷
- The frontal sinus arises embryologically from an anterior ethmoid furrow that evaginates into the frontal bone, forming an inverted, pyramidal-shaped, air-filled structure, along the roof of the orbit.^{7,8}
- The anterior table of the frontal sinus varies between 4 and 12 mm and thickens at its inferior extent to form the frontal “beak,” where it forms an articulation with the frontal process of the maxilla.
 - The anterior table is covered by skin, subcutaneous fat, frontalis muscle, and pericranium.
- The posterior table is much thinner and forms the boundary between the sinus cavity and the intracranial space.
- The intersinus septum is a bony partition that divides the right and left frontal sinuses into two sinus cavities with independent drainage pathways.
 - These cavities may be asymmetric in size and can potentially communicate via an intersinus septal cell.

Frontal Recess

- This is an hourglass-shaped space through which the frontal sinus drains.
- The internal frontal ostium is the narrowest segment of this space.
 - It is bordered anteriorly by the frontal beak and posteriorly by the skull base.
- The ostium drains inferiorly into the frontal recess (previously referred to as the nasofrontal duct), a space that is defined by the following limits:
 - Anterior—frontal beak and posterior wall of the agger nasi cell
 - Posterior—anterior face of the ethmoid bulla
 - Lateral—lamina papyracea and lacrimal apparatus
 - Medial—lateral lamella of the cribriform plate, middle turbinate, and uncinate process^{7,8}

Frontal Pneumatization Patterns

- The anterior ethmoid cells may pneumatize in various patterns, thus resulting in a multitude of different orientations of the frontal sinus outflow tract.
- The development of these cells may lead to displacement of the frontal recess, thus resulting in a circuitous pattern of drainage.
- Agger nasi cell: the most anterior and most anatomically consistent anterior ethmoid cell, located between the lateral nasal wall and the uncinate process, directly anterior to the vertical attachment of the middle turbinate to the skull base (**FIG 1**)
- Type 1 frontal cell: a single cell located superior to the agger nasi cell. Its posterior border displaces the frontal recess posteriorly.
- Type 2 frontal cell: two or more stacked cells located superior to the agger nasi cell. These cells result in posterior displacement of the frontal recess.
- Type 3 frontal cell: a single, large anterior ethmoid cell superior to the agger nasi cell that extends superiorly beyond the internal frontal ostium, into the frontal sinus. It posteriorly displaces the frontal recess.
- Type 4 frontal cell: a single anterior ethmoid cell located entirely within the frontal sinus. Its anterior wall is either the anterior table of the frontal sinus or the floor of the frontal sinus.

FIG 1 • Illustration of the named ethmoid cells, on parasagittal view. Demonstrated is the frontal recess

(*FR*), which is bordered anteriorly by the agger nasi cell (*AN*) and posteriorly by the frontal bullar cell (*FB*). The agger nasi cell is a reliable landmark, present in virtually all sinonasal cavities. Also shown are the uncinate process (*U*, *dashed line*), suprabullar cell (*SB*), ethmoid bulla (*B*), posterior ethmoid cells (*P*), basal lamella of the middle turbinate (*M*), and the sphenoid sinus (*S*).

- Supraorbital ethmoid cell: one or more anterior ethmoid cells that pneumatize superiorly into the frontal sinus. This is typically posterior and lateral to the frontal recess, resulting in anteromedial displacement of the drainage pathway. It may result in a septate appearance of the frontal sinus on coronal imaging.
- Frontal bullar cell: an anterior ethmoid cell located above the ethmoid bulla that extends into the frontal sinus. It borders the skull base and posterior table of the frontal sinus, causing anterior displacement of the frontal recess. It is thought to arise from pneumatization of the lamella of the anterior ethmoid bulla (see **FIG 1**).
- Suprabullar cell: an anterior ethmoid cell located above the ethmoid bulla that borders the skull base. Similar to the frontal bullar cell, it forms from pneumatization of the bulla lamella and displaces the frontal recess anteriorly. It does not, however, extend into the frontal sinus (see **FIG 1**).
- Intersinus septal cell: a pneumatized partition of the frontal sinus septum that drains inferiorly into one of the paired outflow tracts.^{7,8}

Soft Tissue Anatomy

- The afferent innervation of the frontal region is supplied by distal ramifications of the ophthalmic branch of the trigeminal nerve, the supratrochlear and supraorbital nerves.
- The supratrochlear nerve is the medial branch of the frontal nerve.
 - It courses superior to the trochlea (within the orbit) and penetrates the orbital septum at the medial aspect of the orbit.
 - The nerve then traverses the corrugator muscle to provide sensory innervation to the soft tissues of the inferomedial aspect of the forehead.
- The supraorbital nerve is the lateral division of the frontal nerve.
 - It exits the orbit through the supraorbital foramen, at the junction between the

medial one-third and lateral two-thirds of the orbital rim.

- It courses superiorly deep to the corrugator muscle and penetrates the frontalis muscle to provide sensory innervation to the upper and lateral forehead.
- Its distal branches enter retrograde through the anterior table of the frontal sinus (along with the diploic veins) to provide afferent innervation to the sinus cavity.

PATHOGENESIS

- The function of the frontal sinus is not known, but is thought to increase the surface area of respiratory mucosa for air humidification and serves as a protective barrier to forces directed toward the anterior cranium.
- The frontal sinus is lined by pseudostratified, ciliated, columnar epithelium.
- Mucocoeles are lined by the same respiratory-type epithelium, but their exact pathogenesis remains unknown.
- They are believed to arise from mucosal inflammation causing obstruction of the natural drainage pathway of the sinus in which they originate. This leads to retained secretions and osteolysis of the surrounding bone, thus resulting in the expansion that is often noted radiographically.^{2,6,9}
- Insults that lead to ostial obstruction vary considerably and include⁹
 - Trauma
 - Chronic sinusitis
 - Nasal polyposis
 - Iatrogenic (postsurgical)
 - Neoplasm

NATURAL HISTORY

- Due to their pathogenesis, frontoethmoidal mucocoeles tend to be slow-growing, with clinical manifestations occurring late in the disease process.²
- Alternatively, some mucocoeles remain completely asymptomatic and are only discovered incidentally through radiographic imaging for unrelated issues.
- Various series that have looked at postoperative complications from sinus surgery support the indolent nature of frontal mucocoele formation. They have found a mean duration to symptom onset of 5 years following the initial surgery.¹⁰
- Because of this, many of these lesions go unrecognized and may present dramatically with serious complications, due to intraorbital or intracranial

extension.

- Mucocoeles occurring secondary to antecedent trauma to the frontal sinus have been reported up to 50 years following the initial injury.^{1,11,12}
- The peak incidence of these lesions remains unknown. Therefore, all patients who have had any history of frontal sinus trauma are at risk for this late stage complication.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Because of indolent growth patterns, frontal mucocoeles tend to be asymptomatic for many years prior to their clinical presentation.
- They typically become clinically evident only after extensive expansion and erosion, due to compression of surrounding structures.
- Symptomatically, patients most often present with proptosis (61.5%), frontal pain/pressure (38.5%), and nasal drainage (38.5%).⁶
- Less commonly, patients may also experience headaches, nasal obstruction, diplopia, lid swelling, loss of visual acuity, and orbital cellulitis.^{4,6}

IMAGING

- Imaging is typically obtained in the axial, coronal, and sagittal planes, in order to demonstrate the location of the lesion and its relationship to the surrounding anatomical structures.
- CT scan of the maxillofacial skeleton with fine cuts through the paranasal sinuses is the standard imaging modality used in the diagnosis of frontal mucocoeles.
- Contrast enhancement may be utilized to better delineate the degree of intracranial or intraorbital extent and to differentiate these lesions from other pathologic entities.
- CT provides excellent bony definition and typically demonstrates a cystic, homogenous, fluid-filled structure with thinning of the surrounding bone (**FIG 2A,B**).
- MRI may be used in tandem with computed tomography, particularly if the diagnosis remains in question.
- The T2 sequence will reveal a hyperintense signal, consistent with a mucocoele's high fluid content.^{4,11}
- Alternatively, in lesions that have higher protein content, the T2 sequence images may demonstrate an isointense or hypointense signal.

- Postcontrast T1 sequence images may be used to identify dural enhancement, if there is evidence of skull base erosion (**FIG 2C,D**).

DIFFERENTIAL DIAGNOSIS

- Epidermoid cyst
- Dermoid cyst
- Cholesterol granuloma
- Fibrous dysplasia
- Encephalocele
- Meningoencephalocele
- Allergic fungal rhinosinusitis
- Inverted papilloma
- Nasal polyps

SURGICAL MANAGEMENT

- Three approaches will be discussed:
 - Endoscopic, endonasal marsupialization
 - Frontal sinus trephination
 - Combined open and endoscopic decompression

Preoperative Planning

- Sinonasal endoscopy plays a critical role in the evaluation of these patients.
- Purulent secretions may be seen emanating from the middle meatus and draining posteriorly into the nasopharynx.
- In the case of very large lesions, the uncinate process may be expanded medially, with obliteration of the middle meatus.
- Alternatively, if lesions are well-encapsulated or localized to the superior aspect of the sinus, the sinonasal endoscopy may appear completely normal.
- Ophthalmologic evaluation should be requested in any patient with ocular symptoms or radiographic evidence of orbital extension.
- Include a baseline assessment of visual acuity, extraocular movements, and visual field testing.
- Radiographic review
 - The axial, coronal, and sagittal imaging should be evaluated to determine the extent of the lesion and involvement of surrounding structures.
 - Of particular importance is the anteroposterior (AP) diameter of the frontal

sinus outflow tract, best depicted on the sagittal series.

- This dimension determines the ease with which frontal dissection may occur via the endonasal route.
- A narrow AP diameter is associated with an increased risk for damage to the skull base as well as mucosal stripping during the surgery that can lead to restenosis of the frontal sinus outflow tract.
- Other considerations include
 - Height of the olfactory cleft
 - Dehiscent bone of the posterior table
 - Dehiscent bone of the lamina papyracea
 - Presence of polyps
 - Location of the anterior ethmoid arteries
 - Slope of the skull base
- Preoperative antibiotics: In the acutely infected mucopyocele, preoperative antibiotics are indicated.

FIG 2 • Noncontrast CT scans of the paranasal sinuses in the coronal (**A**) and axial (**B**) planes. There is an expansile mucocoele of the right agger nasi cell and frontal sinus, with thinning of the bone constituting the lamina papyracea and anterior skull base. There is extension of the lesion across the midline, into the left frontal recess. T1-weighted post–gadolinium enhanced images in the coronal (**C**) and axial (**D**) planes demonstrate a heterogeneously enhancing cystic lesion of the right frontal recess, with erosion of the right lamina papyracea and skull base. The heterogeneity of the lesion is likely due to proteinaceous elements within the lesion.

Positioning

- Following induction, the head of bed is rotated 90 to 180 degrees away from anesthesia to permit access to the right side of the patient. The display tower is typically positioned on the contralateral side, opposite the surgeon, to provide an unobstructed view of the monitor.
- The patient should be placed in the supine position with the head of bed in a slightly elevated position relative to the heart. This minimizes blood loss, thus improving visualization.
- Pledgets are soaked in a topical anesthetic/decongestant solution and placed intranasally, to dilate the nasal airway.
- If an external approach or trephination is expected with a combined approach, local anesthetic is instilled into the planned incision sites. 1% lidocaine with epinephrine 1:100 000 is generally used.
- Any of the commercially available image guidance systems is acceptable and appropriate for use. The preoperative imaging should be formatted appropriately for use with the chosen guidance system.
- The use of an electromagnetic-based system requires fixation of a patient tracker that may limit access to the forehead, if an external approach is planned.¹³
- In this case, an infrared navigation system with line-of-sight registration may be preferred.¹³

Approach

- The surgical approach should be tailored to the extent of the mucocele and its involvement with surrounding structures.
- The goals of surgery are to marsupialize the mucocele cavity and restore the patency and function of the frontal sinus outflow tract.
- In most cases, this is achieved through an endoscopic approach, with or without removal of the floor of the frontal sinus (Draf IIb or III), depending on the amount of access that is required.¹²
- In the case of a Draf IIb, the floor of the sinus is removed from the supraorbital ridge to the septum, in the midline. This includes excision of the anterior attachment of the middle turbinate to the floor of the frontal sinus.¹²
- In a Draf III, a common cavity defect is created by removing the floor of the bilateral frontal sinuses. This includes the excision of both middle turbinates and the superior aspect of the nasal septum.¹²

- In the case of a superiorly or laterally situated mucocele, a frontal sinus trephination may be performed.

TECHNIQUES

■ Endoscopic Endonasal Marsupialization

- Following induction and positioning, the topical decongestant-soaked pledgets are removed.
- Dissection begins using the zero-degree endoscope.

Uncinectomy

- To access the frontal recess, an uncinectomy is first performed, using backbiting forceps to divide its horizontal and vertical segments (**TECH FIG 1**).
- The vertical segment is bluntly reflected forward and separated from its attachment to the lacrimal crest using the 90-degree Blakesley forceps.
- The horizontal segment is then sharply removed, with through-cutting instruments or a microdebrider. Preserve the basal lamella of the middle turbinate.
- For large lesions, wide exposure is warranted for panoramic exposure of the frontal recess.
- This requires a maxillary antrostomy and anterior ethmoidectomy.
- If there is more extensive involvement or erosion of the orbit, posterior ethmoid dissection may be required as well.

Maxillary Antrostomy and Anterior Ethmoidectomy

- The anterior fontanelle is identified and dilated, using the maxillary ostium seeker.
- The membranous medial wall of the maxillary sinus is taken down with straight through-cutting forceps, thus connecting the anterior and posterior fontanelles.
- A 45-degree angled endoscope should be used for greater visualization of the surgical antrostomy. This ensures that the surgical antrostomy is in continuity with the natural ostium of the maxillary sinus, thus avoiding postoperative

recirculation.

- The ethmoid bulla is a reliable landmark that is easily identified after the uncinectomy has been performed. It forms the posterior aspect of the frontal sinus outflow tract.
- It is removed via a retrobullar approach.
- A J-curette is placed into the sinus lateralis or retrobullar space and the bulla is dissected anteriorly and removed (**TECH FIG 2**).

TECH FIG 1 • Uncinectomy. The backbiter (*BB*) is placed within the hiatus semilunaris and used to transect the horizontal from the vertical portion of the uncinate process, thus opening the maxillary antrum. NS, nasal septum; MT, middle turbinate; LC, lacrimal crest; EB, ethmoid bulla.

TECH FIG 2 • Anterior bulllectomy. The J-curette (*JC*) is placed within the sinus lateralis (*SL*), the space immediately posterior to the ethmoid bulla (*EB*). The bulla is disarticulated from the lamina papyracea (*LP*)

and skull base, thus opening the anterior ethmoid cavity. MA, maxillary antrum; IT, inferior turbinate.

Frontal Dissection

- With the anterior ethmoidectomy and maxillary antrostomy completed, frontal dissection is performed using the 45-degree endoscope.
- The anterior ethmoid artery is identified along the skull base, coursing from posterolateral to anteromedial.
- It is critical to identify this structure, as it marks the posterior limit of the frontal sinus outflow tract, approximately 2 to 5 mm posterior to the opening. Inadvertent injury to this structure may result in retraction of the lateral stump of the artery into the orbit, causing an orbital hematoma.
- The frontal sinus outflow tract is identified and widened using frontal sinus (Bolger-Kuhn) probes or curettes, which are specifically angled for this purpose (**TECH FIG 3A**).
- The tract is typically located posterior and medial to the agger nasi cell. In two-thirds of patients, it drains lateral to the uncinate process and into the ethmoid infundibulum.
- The agger nasi cell is removed in a posterior-to-anterior direction. Avoid inadvertent entry into the intracranial space through the posterior table of the frontal sinus.
- The horizontal table of bone along the anterior and medial aspect of the frontal drainage pathway is safe for resection. The posterolateral mucosa is left intact to permit re-epithelization of the frontal outflow tract.
- Removal of the floor of the frontal sinus is best performed using a combination of grasping and through-cutting giraffe forceps (**TECH FIG 3B**), curved rongeurs (eg, angled Kerrison 45 or 90 degrees), and Hosemann through-cutting punch forceps (**TECH FIG 3C**) or with angulated, powered drills to widely marsupialize the mucocoele cavity.
- 90-degree giraffe forceps are used to remove all free-floating fragments.
- Culture and Gram stain are obtained once the mucocoele cavity is drained, to direct the choice of postoperative antibiotics.
- In general, if there is significant lateral or superior extension of the mucocoele, the entire floor of the frontal sinus is removed, from orbit to the midline and posteriorly to the location of the first olfactory filament (Draf IIb).¹²

- In lesions that cross the midline, a superior septectomy with resection of the floor of the contralateral frontal sinus and partial septectomy is performed (Draf III) (**TECH FIG 3D**).

TECH FIG 3 • **A.** Frontal curettes used to enter into and widen the frontal recess to allow the use of other curved instruments. **B.** Kuhn frontal sinus forceps, designed to sharply cut or grasp ledges of bone for removal from the frontal sinus outflow tract. **C.** Frontal rongeurs, used to amputate dense or osteitic bone from the frontal recess, when delicate instrumentation is insufficient. **D.** Endoscopic view of a Draf III frontal sinusotomy defect. The *dashed line* indicates confluence of the right (*F*) and left (*f*) frontal sinus outflow tracts after removal of the superior aspect of the nasal septum and the leading edge of the bilateral middle turbinates.

Completion

- If the skull base and orbit are not dehiscent, the sinus cavity is irrigated with buffered saline solution to remove all debris and infectious contents.
- Visualization is achieved using the 70-degree endoscope to confirm the

patency of the frontal sinus outflow tract and to ensure that no residual septations exist that may result in postoperative obstruction or scar formation.

- The decision of whether to stent the frontal outflow tract depends on a number of factors that portend a poor prognosis, such as:
 - A-P diameter of the frontal outflow tract less than 8 mm
 - History or presence of nasal polyps
 - Prior recurrence of mucocele
 - Prior history of sinonasal surgery
 - Previous frontal sinus trauma^{14–16}
- A variety of stents are available, including steroid-eluting products that slowly resorb over time.
- Alternatively, a T-shaped stent may be fashioned from a piece of 1/100-in.-thick Silastic sheeting that is rolled and cut to the appropriate length to adequately traverse the frontal sinus outflow tract.
- Hemostasis is then achieved. Packing may be placed but is generally not necessary unless there is a substantial risk of postoperative epistaxis (ie, pre-existing coagulopathy, extensive intraoperative blood loss) or if there is significant destabilization of the middle turbinate that may lead to scar formation.

■ Frontal Sinus Trephination

- In mucoceles that are located laterally and superiorly within the frontal sinus, or those that have caused marked osteoneogenesis of the frontal sinus outflow tract, frontal sinus trephination may be required for extirpation of the infection.

Exposure

- Various incisions have been described, including the suprabrow, intrabrow, and infrabrow.
- The infrabrow is classically described, because it allows for safe entry into the frontal sinus medially and inferiorly, at the broadest and most dependent region of the sinus.
- 1% lidocaine with epinephrine 1:100 000 is injected into the planned surgical site (**TECH FIG 4**).
- The incision extends 1.5 to 2.0 cm horizontally along the inferior margin of the eyebrow beginning at the medial brow tuft.

- Medial extension beyond this point may result in noticeable scarring of the skin.

TECH FIG 4 • Incision sites for trephination. Infrabrow—immediately inferior to the brow, along the orbital rim. Intrabrow—directly through the midportion of the brow. Suprabrow—superior edge of brow.

- Placement of the incision too far inferior may result in trephination of the frontal sinus outflow tract, resulting in postoperative scarring and obstruction.
- The skin is then sterilely prepped and draped.
- The incision is made using a no. 15 blade. It is extended through the skin, subcutaneous tissue, orbicularis oculi and corrugator muscles, and periosteum.
- Hemostasis is achieved with bipolar (rather than monopolar cautery) in order to avoid thermal damage to the skin and periosteum.
- The periosteum is elevated from the frontal bone using a periosteal elevator, thus exposing a 1 × 1 cm area where the osteotomy may be performed.

Osteotomy

- The osteotomy is ideally made at the level of the floor of the frontal sinus (**TECH FIG 5**).
- This avoids the frontal sinus outflow tract, which is located inferiorly; injury to the tract results in postoperative neo-osteogenesis and obstruction.

TECH FIG 5 • The osteotomy is ideally made at the level of the floor of the frontal sinus. Using a 4-mm rough cutting round diamond bur, an approximately 8 to 10 mm of bone of the anterior table is saucerized.

- It also avoids entry into the anterior table of the sinus through which diploic veins course. Exposure of these vessels can cause seeding of the infection from the mucocele cavity, resulting in osteomyelitis of the frontal bone or intracranial extension of the infection.
- The osteotomy is made using a 4-mm rough cutting bur. An area measuring 8 to 10 mm is saucerized on the anterior table, without entry into the sinus cavity.
- The bone is drilled until close proximity to the underlying mucosa is reached.

- A curette is used to enter through the mucosa.
- The osteotomy is widened with the Kerrison rongeur to a diameter of 1 to 1.5 cm, depending on the size required for access to the mucocele and introduction of endoscopic instruments.
- The mucocele is then drained under direct visualization. Cultures are obtained to guide the postoperative antibiotic regimen.
- If the trephination is combined with an endoscopic, endonasal approach, instruments may be introduced transnasally, while visualization is provided from above through the trephination site.
- All bony septations of the mucocele and their associated mucosa are removed with powered drills and/or the Kerrison rongeur.

Completion

- The sinus cavity is then irrigated with buffered saline solution, except in the case of a dehiscence into the orbit or posterior table.
- One-to-two red rubber catheters can be placed through the trephination site to provide a conduit for postoperative irrigation.
 - These are secured with a 4-0 nylon suture to the skin.
 - The periosteum and surrounding soft tissues are closed with 4-0 Vicryl suture.
 - The skin around the drain is closed with interrupted nonresorbable suture.

■ Combined Endonasal-External Approach

- The above-mentioned approaches may be used in tandem for cases in which there is more extensive disease that does not lend itself to a single approach.
 - Trephination is rarely performed as a stand-alone procedure, as the likelihood of recurrence of the mucocele is high.
 - Marsupialization via trephination combined with the creation of a permanent drainage pathway via an endoscopic frontal sinusotomy provides a more permanent solution for frontal sinus mucoceles.
 - Other approaches to the frontal sinus, including osteoplastic flap and bicoronal approach, are covered elsewhere in this text.
-

PEARLS AND PITFALLS

Visualization	■ Endoscopic visualization of the frontal recess is difficult, even in the trained surgeon's hands. ■ Use of the 70-degree endoscope may improve visualization, by providing a more panoramic view of the frontal sinus outflow tract. ■ This will help to avoid mistaking a supraorbital ethmoid cell for the frontal sinus, thus ensuring proper dissection.
Mucosal stripping	■ Use through-cutting instrumentation, in order to avoid damage to the posterior and lateral mucosa of the frontal sinus outflow tract. ■ Failure to do so may result in extensive postoperative scar formation and disruption of mucociliary clearance of the sinus cavity.
Hemostasis	■ Obtain hemostasis prior to the reversal of anesthetic because of the fluctuations in blood pressure that may occur during this process. ■ Multiple hemostatic agents are commercially available that are effective in controlling mild oozing. ■ Brisk, arterial bleeding must be controlled with monopolar or bipolar cautery. ■ Avoid injury to the sphenopalatine and anterior ethmoid arteries. ■ Prior to reversal, a Valsalva maneuver should be performed to confirm that there is no persistent bleeding. ■ Resorbable or nonresorbable packing may be placed within the middle meatus for hemostasis. ■ Avoid vasoconstrictive agents toward the end of the case. This may conceal areas of active bleeding that will rebleed following reversal.

POSTOPERATIVE CARE

- Endoscopic, endonasal marsupialization
 - In cases approached endoscopically, postoperative care includes systemic antibiotics, and possibly steroids, depending on the amount of mucosal inflammation and polyposis noted at surgery.¹⁷
 - Patients are uniformly placed on 2 to 3 times daily sinonasal irrigation with a buffered saline solution to remove debris and promote mucosal healing.¹⁷
 - This may be impregnated with steroid and/or antibiotics, depending on the degree of polyposis and the culture result and sensitivity profile.¹⁷

- Patients are seen at 1 to 2 weeks postoperatively for the first debridement, which is performed endoscopically in the outpatient setting, with a topical anesthetic.
 - If packing was placed intraoperatively, it is removed at this time with a straight Blakesley forceps.
 - If a nonabsorbable stent was placed in the frontal recess, it is typically removed at the first postoperative visit but may be left longer if there is a significant concern for scarring of the frontal outflow tract.^{14–16}
- Patients are seen in the office every 2 to 3 weeks and examined using the endoscope for the first three months. Follow-up is then performed every 3 months for the first year and every 6 to 12 months thereafter.^{4–6}
- Frontal sinus trephination
 - Antibiotic ointment is placed on the drain twice daily until the first postoperative visit.
 - The external drains are irrigated 1 to 2 times daily with buffered saline solution for 3 to 5 days.
 - The drains are then removed and the surrounding skin defect is left to heal by secondary intention. Nonresorbable skin sutures are removed at 5 to 7 days postoperatively.

OUTCOMES

- Endoscopic drainage of sinonasal mucoceles has a high success rate, with a low rate of recurrence.¹⁸
- Studies evaluating lesions that are amenable to endoscopic drainage have reported long-term recurrence rates of 0% to 11%.^{4,9}
- In these cases, repeat endoscopic evaluation is critical in the surveillance of these patients for disease recurrence.
- External approaches are associated with a higher risk of recurrence, likely owing to the severity of the lesion or its location (making endoscopic detection difficult).
- Reported rates of recurrence for external approaches may be as high as 6.8% to 23.5%.²

COMPLICATIONS

- Complications associated with endoscopic, endonasal marsupialization of frontal mucoceles are similar to those associated with endoscopic sinus surgery.
- These risks include both major and minor complications.

- Major complications:
 - Orbital injury
 - CSF leak
 - Severe hemorrhage
 - Nasolacrimal duct injury
 - Meningitis
- Minor complications:
 - Minor hemorrhage
 - Violation of the lamina papyracea
- Overall, the incidence of complications is between 0.9% and 23%.^{19,20}
- The risk of complications is increased with revision surgery, as compared to primary surgery.
- External trephination is subject to the same complications as the endoscopic approach, but also has additional associated risks, including:
 - Hypesthesia of the forehead
 - Refractory pain
 - Poor cosmesis due to scarring and contour deformity

Section VII: Orbital Trauma

Correction of Orbital Floor Blow-out Fractures: Variation 1

53
CHAPTER

Jean-Francois Lefaivre and David Charles A. Fisher

DEFINITION

- Orbital blow-out fractures commonly result from force directly applied to the globe with subsequent energy transmission through the thin surrounding bones. The affected bones are typically the orbital floor and medial wall. It may be accompanied by entrapment of the inferior rectus muscle and inferior oblique muscle. True entrapment is a rare clinical finding. It is often mentioned on radiology reports and must be differentiated from herniation.
- Orbital floor fractures are often associated with additional facial fractures and soft tissue injury.

ANATOMY¹

- The orbital floor is composed of thin maxillary and zygomatic bone. Anteriorly, just behind the orbital rim, the floor is concave and becomes convex, posterior to the axis of the globe. It is bordered laterally by the lateral orbital wall, which is relatively thick, and consists of the frontal process of the zygoma, and greater and lesser wings of the sphenoid. Medially, the floor slopes upward toward the medial orbital wall, which is also a thin bony structure, made of the frontal bone superiorly, lacrimal bone anteriorly, and lamina papyracea of the ethmoid and lesser wing of the sphenoid posteriorly. The lamina papyracea, as its name implies, is thin and fragile.
- The inferior orbital fissure is located between the orbital floor and lateral

orbital wall. Structures present in the fissure include the maxillary division of the trigeminal nerve, infraorbital artery, zygomatic nerve, branches of the sphenopalatine ganglion, and branches of the ophthalmic vein. The inferior orbital fissure is also known as the sphenomaxillary fissure (**FIG 1**).

- The orbital plate of the maxilla and a portion of the zygoma represent the orbital floor. The zygoma makes up the anterior portion of the orbital floor, anterior to the inferior orbital fissure. The infraorbital nerve runs through the orbital floor in the infraorbital groove posteriorly and in the infraorbital canal anteriorly. The nerve often provides a landmark and a good plane of dissection.
- The infraorbital rim is made of zygomatic bone and maxilla. The frontal zygomatic suture is exposed during dissection. Just inferior to the inferior orbital rim, the infraorbital foramen is located about 1 cm below the rim, generally in line with the midaxis of the pupil.
- Both the orbital floor and medial orbital wall are vulnerable to injury because they are relatively thin compared to the surrounding structures.
- Knowledge of anatomy is essential to perform safe dissection and optimal exposure of the orbital floor defect.

PATHOGENESIS

- Orbital blow-out fracture is often the result of blunt injury to the globe and/or orbital rim, sustained during altercations, falls, sports-related injury, or motor vehicle accidents. These injuries transmit an external force to the orbital contents and orbital bones. The weakest portion of the orbit then fractures, resulting in herniation of orbital contents through the bony defect. The anterior and posterior portions of the orbital floor are thicker. The middle portion of the orbital floor is thinner, which accounts for the majority of fractures into the maxillary sinus. The medial orbital wall also commonly fractures into the ethmoid sinus air cells.
- The globe typically moves posteriorly, inferiorly, and medially if there is significant prolapse or herniation of the orbital content into the orbital floor defect.

FIG 1 • Anatomy of the left orbit.

NATURAL HISTORY

- Untreated fractures generally result in enophthalmos. Depending on the volume increase associated with orbital fracture, it will range from minimally to significantly noticeable. Enophthalmos can be identified clinically with 2 mm of posterior displacement of the globe.² A 5% increase in orbital volume is sufficient for a clinical diagnosis of enophthalmos.² An important part of informed surgical consent is to discuss the anticipated natural history of untreated defects. Hypoesthesia in the distribution of a second branch of the trigeminal nerve generally resolves over several months. Diplopia may improve if it is secondary to muscle contusion.
- If an entrapped muscle is not treated promptly, permanent ischemic injury to the extraocular muscle will result in diplopia. It is the only emergency associated with orbital floor fractures. Our experience, as previously reported, is that it is more common in children than in adults.
- Retrobulbar hematoma that results in optic nerve compression is an emergency; however, in a blow-out fracture, there is typically an expanded volume that alleviates the pressure on the orbital apex.

- Patients with large orbital floor defects are generally treated acutely secondary to obvious enophthalmos. Patients with more subtle findings may be observed initially and surgically treated when/if they develop enophthalmos. These are generally patients with smaller defects on computed tomography (CT) scans.³
- The decision of whether or not to operate can generally be made within the first 6 weeks following injury. Longer follow-up may be recommended in patients managed nonoperatively.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Specific trauma-related history helps elucidate the amount of force transmitted to the globe and orbit.
- Previous eye surgery, eye injury, or pathology should be documented as well as the use of prescription glasses or contact lenses.
- Physical examination often reveals
 - Periorbital ecchymosis and swelling
 - Subconjunctival hemorrhage
 - Enophthalmos, most easily identified by both a worm's eye and a bird's eye view; may be masked by edema early after injury
 - Diplopia, often in upward gaze
 - Hypoesthesia in the distribution of the second branch of the trigeminal nerve, involving the cheek, nose, upper lip, gingiva, and upper teeth in various distributions
- Visual acuity, extraocular movements, and pupil examination need to be assessed
- Preoperative consultation with ophthalmology may be beneficial, especially in patients with decreased visual acuity or retrobulbar hemorrhage.

IMAGING

- Orbital or maxillofacial CT scan with 1 to 2 mm axial cuts and coronal and sagittal cuts will help understand the size and location of the defect, as well as soft tissue herniation. It will help determine the length and width of the bone graft or implant required for adequate repair⁴ (Video 1).

Video p2-c053_01

- A three-dimensional (3D) reconstruction is often beneficial in patients with multiple associated facial fractures. It is not essential for isolated orbital floor fractures.

DIFFERENTIAL DIAGNOSIS

- Medial orbital wall fractures may result in similar findings.
- Medial orbital wall defects should be identified preoperatively.
- Surgical treatment of orbital floor fractures that do not address associated medial floor fractures will result in only partial correction of enophthalmos.

NONOPERATIVE MANAGEMENT

- Small defects without herniation of orbital contents and without entrapment may be managed conservatively with close follow-up.

SURGICAL MANAGEMENT

- The primary objective of surgical intervention is to recreate normal anatomy with restoration of the orbital floor integrity and reduction of herniated soft tissue into normal position. Restoration of orbital shape and volume should help rebalance extraocular muscles and correct diplopia.
- Indications to correct orbital floor fractures include the following:
 - Enophthalmos
 - Large orbital floor defects with herniation on CT scan. Some authors mention that a 1 to 2 cm² defect or 50% of the orbital floor surface will result in enough orbital volume increase to result in clinically significant

enophthalmos.^{2,3}

- Diplopia associated with entrapment
- Entrapment with positive forced duction test. Extraocular muscles recover better if surgically released within 48 hours.
- Persistent oculocardiac reflex may be associated with soft tissue entrapment. Patients who benefit from early surgical intervention are those presenting with nausea, vomiting, and bradycardia, exacerbated with upward gaze.²

Preoperative Planning

- Complete review of the chart including medications is important, particularly anticoagulants.
- If long-acting dilating eye drops are used by ophthalmology, it is generally recommended to wait before taking the patient to the operating room. Pupil diameter is assessed preoperatively. If a pupil dilates intraoperatively, it is often secondary to excess retraction. This phenomenon cannot be observed in patients with pupils pharmacologically dilated.
- If the patient has a retrobulbar hematoma, clearance from ophthalmology prior to surgery is recommended.
- A thorough eye examination should be performed by the plastic surgeon and documented in the chart preoperatively.⁵
- Clearance from trauma team, neurosurgery, and other consultants is obtained prior to surgery.
- Timing of surgery depends on associated injuries. It may be beneficial to wait a few days and operate after periorbital swelling improves.
- CT scans are reviewed. The decision to proceed with bone grafts and titanium or resorbable implant is often made preoperatively. Other types of implants have been associated with complications such as extrusion³ (Video 1).
- Informed consent is obtained. Risks, goals, and benefits are explained to the patient or family members. Risks include bleeding, infection, scar, ectropion, diplopia, residual enophthalmos, hypoesthesia, need for additional surgery, and blindness.

Positioning

- Patient is in supine position, operating room table rotated 90 or 180 degrees.
- Vertex should be aligned with the head of the bed. This will help decrease surgeon fatigue and discomfort.

- In patients without cervical injury, the head of the bed could be slightly extended to better visualize the orbital floor.
- In patients with cervical injury, the cervical collar is left in place and the whole table can be placed in Trendelenburg to help visualize the orbital contents.
- A headlight is essential. Battery-powered headlights provide more freedom, allowing the surgeon to review the CT scan if necessary and to evaluate the patient in worm's eye and bird's eye views alternatively.
- Loupe magnification is based on preference.
- Operating room monitor with ability to project CT scan is also helpful.
- Sequential compression devices and body warmers are applied to all patients unless contraindicated.

Approach

- Subtarsal incision or transconjunctival incision provides adequate exposure.
- The subciliary incision carries a higher risk of ectropion and should be avoided.³
- The subtarsal incision is rapid, reliable, and easy to learn. It is also easier if one has to reoperate in a complex panfacial fracture patient. The key step is to preserve a strip of pretarsal orbicularis muscle to decrease the likelihood of postoperative ectropion.
- When using a transconjunctival incision, a modified lateral canthotomy^{6,7} is helpful. This gives better exposure than does a regular transconjunctival approach and avoids a lateral canthotomy. Entropion is a rare complication associated with the transconjunctival approach.⁸
- With either incision, the surgeon must visualize all edges of the floor defect.

TECHNIQUES

■ Markings and Preparation

- Marking is made in the preoperative holding area in a natural eyelid skin crease for subtarsal approach (**TECH FIG 1A–C**).
- General anesthesia with an oral RAE tube improves surgical access compared to a regular orotracheal tube. If a regular tube is used, it is taped to the chin. For patients with multiple facial fractures, the orotracheal tube is

often wired to a permanent bicuspid or molar. If the patient has maxillary and/or mandibular fractures requiring intraoperative assessment of occlusion, a nasal RAE tube is used and secured to the nasal septum with a 0-silk suture.

- Infiltration of lidocaine 1% with epinephrine 1:100 000 on the lower lid and over the infraorbital rim prior to prepping and draping allows enough time for effective vasoconstriction.
- After prepping and draping, the eyes are thoroughly irrigated with balanced salt solution. Normal saline solution is generally avoided because the pH may not be balanced.
- Forced duction test is performed as a baseline.
- Corneal protector and ocular lubricant are applied.
- Tension is applied on the lower lid through either traction sutures or a double-pronged skin hook pulling superiorly and away from the globe (**TECH FIG 1D**).

TECH FIG 1 • A. Planned incision in a natural skin

crease, below the level of the tarsal plate and below the pretarsal orbicularis muscle. It can be extended laterally in the crow's feet to provide better exposure. **B.** The incision is drawn in a natural skin crease and extends laterally and downward in the crow's feet. **C.** By pulling downward on the eyelid, it is easy to see that the pretarsal portion of the orbicularis oculi muscle will be preserved. **D.** The surgeon is standing at the head of the bed. This will allow better access to the orbital floor. Once a corneal protector is in place, the double hook is used to apply tension upward on the lower lid while the assistant pulls downward to apply countertraction while the incision is made through skin only. The blade is then placed tangential to elevate skin from the orbicularis muscle. An incision through the orbicularis muscle is made lower than the skin incision with the tenotomy scissors.

■ Exposure

- Subtarsal skin incision with no. 15 blade
- The blade is turned tangential to the skin to elevate skin over the underlying orbicularis oculi muscle for a few millimeters.
- Curved iris scissors are used to split the orbicularis muscle parallel to fibers, exposing the underlying preseptal plane. This is a stepped approach with orbicularis oculi incision slightly below the level of the skin incision.
- Meticulous hemostasis is provided with electrocautery through an insulated needle tip at a low setting or with bipolar cautery.
- Blunt dissection is performed with a finger down to the infraorbital rim in an avascular plane. Good exposure of the infraorbital rim is provided (**TECH FIG 2A–C**).

TECH FIG 2 • A. Suborbicular dissection proceeds to the infraorbital rim. Gentle traction with skin hooks provides excellent exposure. **B.** This plane is relatively bloodless, following areolar tissue. **C.** The inferior orbital rim is exposed. Corneal protectors are always used when skin hooks are used to retract tissue around the eye. **D.** Once the inferior orbital rim is exposed, the malleable retractor is placed over the orbital contents and a Desmarres eyelid retractor is used to retract the lower lid. Electrocautery is used to incise the periosteum. **E.** An assistant holds the Desmarres retractor while the surgeon holds the malleable and periosteal elevator to expose the defect.

- Infraorbital rim periosteum at the anterior edge is incised with electrocautery (**TECH FIG 2D**).
- Subperiosteal dissection is initiated over the anterior edge of the infraorbital rim, from medial to lateral, followed by intraorbital subperiosteal dissection. Wide subperiosteal dissection, often well beyond the fracture site,³ is required to provide adequate exposure of the defect.
 - An orbital retractor or malleable retractor is used to gently retract the orbital contents away from the floor (**TECH FIG 2E**).
 - A graduated orbital retractor helps determine how far into the orbit the dissection extends. The orbital apex is typically 45 mm from the infraorbital rim. This distance should be kept in mind as one dissects from anterior to posterior. Most orbital floor fractures will be within 30 to 35 mm from the infraorbital rim. This should have been measured preoperatively on the CT scan.
- Bradycardia may be encountered if too much pressure is applied to the globe. If this occurs, retractors are removed until the heart rate normalizes. Ongoing communication with the anesthesia team is essential.
- The corneal protector is removed to assess whether the pupil has dilated secondary to retraction/pressure on the globe. If this is the case and there are no medical contraindications, intravenous dexamethasone may be used intraoperatively and postoperatively for 24 to 48 hours.
- Dissection also includes reduction of all herniated soft tissue. There is generally an areolar plane over the infraorbital nerve. Avoid grasping the nerve while reducing orbital contents.
- Hematoma inside the maxillary sinus is aspirated. Irrigation of saline or bacitracin solution is also helpful in draining maxillary sinus hematoma.
- Use of 1 × 3-in. neuropledgets can help hold intraorbital fat and assist with exposure. They can be soaked in epinephrine solution to aid in hemostasis.

■ Implant Placement and Completion

- The orbital floor defect is measured. It should correlate with preoperative measurements based on CT scan. An implant slightly longer and wider than the defect is chosen. It may have to be cut to the desired size.
- The bone graft or implant is carefully applied (**TECH FIG 3A**; Video 2), making sure that it rests over the posterior ledge of the defect and does not

prolapse into the maxillary sinus. It should extend 1 or 2 mm beyond the posterior ledge. A longer implant or graft may impinge on the posterior aspect of the inferior rectus muscle or orbital apex structures.

Video p2-c053_02

- The graft or implant must be properly positioned (**TECH FIG 3B,C**). This is the most critical portion of the procedure.
- Enophthalmos should be corrected. The globe position will appear slightly overcorrected because of intraoperative swelling.
- A forced duction test is repeated to be certain there is no entrapment (**TECH FIG 3D**; Video 3). The globe is rotated upward to make sure that there is no inferior rectus muscle entrapment. The globe is also moved laterally to make sure that there is no medial rectus muscle entrapment in the case of associated medial orbital wall fractures. The corneal protector is removed to perform this test and reapplied afterward.

Video p2-c053_03

TECH FIG 3 • A. Once the defect is completely exposed, a bone graft or titanium implant is placed to bridge the defect. **B.** Titanium orbital floor implant similar to the one used in surgery. The medial extension “M” and the anterior four extensions are cut prior to inseting. **C.** Titanium orbital floor implant in place; left orbit with suction tip in medial position and malleable retractor holding the orbital content. The anterior edge of the implant is behind the inferior orbital rim. Note that the plate has been trimmed to cover the defect. **D.** A forced duction test is performed after the implant or bone graft is placed on the orbital floor. It is better to perform a forced duction test before surgery, as a baseline, to be able to better appreciate changes following the procedure.

- Irrigation with bacitracin solution
- Closure of the periosteum with resorbable suture such as 3-0 or 4-0 Vicryl suture
- Hemostasis is re-evaluated.

- The orbicularis muscle is redraped.
- Orbicularis muscle may be resuspended laterally to the periosteum of the lateral orbital rim to provide support.
- Skin can be closed with a running 5-0 Prolene suture or with 6-0 interrupted fast-absorbing gut suture.
- Corneal protector is removed. Eyes are irrigated again with balanced salt solution.
- Temporary tarsorrhaphy may be applied through the gray line, lateral to the lateral limbus with 6-0 Vicryl or 5-0 plain gut suture in patients on whom postoperative chemosis could be a concern.
- Eyes are thoroughly irrigated with balanced salt solution.
- Lacri-Lube or ophthalmic ointment is applied in the eye and over the suture line.
- Frost suture is applied to provide gentle traction to the lower lid. It is removed 48 to 72 hours after surgery, after swelling improves.
- At the completion of procedure, communication with the anesthesia team is essential in order to avoid Valsalva, traumatic emergence from anesthesia and perioperative hypertension.

PEARLS AND PITFALLS

Physical findings

- Enophthalmos may not be obvious initially because of swelling. Decreased range of motion of extraocular muscles does not mean entrapment. Entrapment is rare. Oculocardiac reflex should raise the suspicion for entrapment. A forced duction test can be used in selective cases to rule out entrapment. Visual acuity should be assessed preoperatively.

Technique

- It is important to dissect the orbital floor to expose the entire defect to make sure that anatomic repair is achieved. Placement of plate or bone graft should be done under direct vision to make sure that it covers the posterior ledge of the defect without going too far posteriorly. An intraoperative forced duction test helps ensure that there is no entrapment after the plate or bone graft is applied.

Postoperative care

- Failure to recognize and address a retrobulbar hematoma may result in decreased visual acuity.

POSTOPERATIVE CARE

- Patients are generally observed overnight, with the head of the bed elevated 30 degrees. Most patients without concomitant injuries are discharged the morning after surgery.
- Extraocular movements and visual acuity need to be evaluated soon after surgery.
- If a Frost suture or a tarsorrhaphy suture is placed, it is generally removed after 48 to 72 hours, when swelling starts to resolve.
- Periorbital edema is expected as well as blurred vision secondary to ocular edema. If there is any significant decrease in visual acuity, the patient may have a retrobulbar hematoma. This is a surgical emergency, requiring decompression of the orbit in order to prevent blindness.
- Patients should avoid nose blowing early after surgery because there is a risk of pneumo-orbit with air extending to the soft tissue envelope. Over-the-counter nasal spray is recommended postoperatively.
- Lacri-Lube is recommended for patients who cannot completely close their eyelids.
- A postoperative CT scan may be indicated if there is any question about residual enophthalmos (Video 4). Diplopia is often seen early postoperatively and usually gets better over a few weeks, sometimes a few months. Patients should do range-of-motion exercises. If diplopia persists, ophthalmology consultation is indicated.

Video p2-c053_04

- If the patient develops ectropion, massaging the eyelid is recommended.

OUTCOMES

- With anatomic repair, there should not be residual enophthalmos. Extraocular movements should be intact unless there has been injury to the infraorbital portion of the oculomotor nerves or extraocular muscles, as a result of either trauma or surgery.
- Extraocular movements are often limited postoperatively and generally improve with time. If diplopia persists beyond a few weeks after surgery, ophthalmology consultation is indicated.
- Scars heal nicely following transcutaneous incision or transconjunctival approach. Although ectropion can be seen following transcutaneous approaches, entropion can be seen following a transconjunctival incision.⁶

COMPLICATIONS

- Hematoma may involve the lower lid, in the area of dissection. It can also be located in a retrobulbar location, leading to increased pressure around the optic nerve. This emergency needs to be recognized early and addressed surgically with lateral canthotomy to decompress the orbit. Lower lid hematoma can be aspirated once the hematoma liquefies but generally reabsorbs on its own. Lower lid hematoma may increase the risk of postoperative lower lid retraction and ectropion.¹
- Cicatricial ectropion can be seen postoperatively even if the pretarsal muscle is preserved. Commonly, this will resolve with massage and time.
- If lagophthalmos develops, ocular lubricants and nighttime taping are essential to prevent corneal ulceration.

Correction of Orbital Floor

54 Blow-out Fractures: Variation 2

CHAPTER

Henry C. Vasconez

DEFINITION

- The orbit is a paired structure of the upper craniofacial skeleton.
- It houses the globe, nerves, vessels, and surrounding soft tissue structures.
- The orbital floor consists of very thin bone and ligamentous structures and therefore is easily fractured when sustaining a significant force.
- Orbital floor fractures can be defined as pure blow-out fractures or impure blow-out fractures (**FIG 1**).¹

ANATOMY

- The orbit is a paired structure that has a conical shape and is separated in the midline by the interorbital structures consisting primarily of the ethmoid and frontal sinuses and the underlying nasal structures.
 - The cone or bony pyramid of the orbit is made up of a roof, floor, and medial and lateral walls.
 - At the apex of the cone posteriorly lie the optic nerve and other important nerves and vessels.
- The orbital floor forms the roof of the maxillary sinus, slopes upward and medially toward the apex of the cone, and has an AP distance of approximately 45 mm.
- The bony orbit volume is approximately 30 cc and the globe is approximately 7 cc.
- The anterior portion of the floor is concave; the posterior portion is convex and is the thinnest part of the floor and sustains most of the fractures.

PATHOGENESIS

- Orbital floor fractures are categorized as pure or impure blow-out fractures.²

FIG 1 • Pure globe-to-wall blow-out fracture (**A**) vs buckling or impure blow-out fracture (**B**).

- There are also linear or cracked and trapdoor fractures as well as comminuted fractures of the floor.
- The type of fracture depends, in large measure, on the vector and amount of force applied to the orbit or surrounding skeletal structures.
- A pure blow-out fracture involves the thin floor and medial and/or lateral walls of the orbit.
- An impure blow-out fracture involves the disruption of the thick orbital rim and, many times, adjacent facial skeletal structures.
- A trapdoor orbital fracture is a pure orbital blow-out fracture, whereby a bony fragment is displaced inferiorly, into the maxillary sinus, while still being hinged. Orbital structures herniate through this defect and become entrapped.
- Orbital contents that can become entrapped include the periocular muscles, commonly the inferior rectus and inferior oblique. Muscle entrapment causes restriction of upward gaze and consequent diplopia.

NATURAL HISTORY

- Significant controversy remains regarding the indications for operative repair

of orbital floor fractures.

- Nondisplaced or mildly displaced orbital floor fractures will tend to do well after edema subsides and the brain adapts to the small visual field discrepancy.
- Diplopia secondary to enophthalmos, significant defects in ocular motility, and significant radiographic findings are all important indications for operative intervention.
- Entrapment of orbital contents, especially in the pediatric age group, can lead to significant, early symptoms, both visual and systemic (including nausea and vomiting), and should be addressed urgently.
- Significant orbital floor fractures that remain untreated can later present problems to the patient and can be very challenging to correct properly.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most orbital floor fractures result from blunt injuries, primarily from motor vehicle crashes or assaults.³
- Signs and symptoms of these fractures include edema and bruising, pain, diplopia, subconjunctival hemorrhage, sensory deficits mostly in the infraorbital region, and, at times, visual deficits.
- Ophthalmology should be consulted with any visual field deficits.
- The position of the globe, including cornea and pupil, is important to assess and compare with the contralateral, uninjured side.
- Extraocular muscle movements are then tested for any pain or deficits.
- In the unconscious patient, extraocular muscle movements can be assessed by performing a forced duction exam, testing for any restriction of muscles or associated structures (**FIG 2**). If possible, this result is compared with the contralateral side.
- Gentle yet thorough palpation of the orbit and its periorbital structures, is performed to identify obvious fractures or step-offs.
- Examination of the pupils is important to identify an optic nerve injury or other afferent pupillary defects. Consensual and accommodation reflexes are also evaluated.
- The oculocardiac reflex is particularly important in children with entrapment of orbital structures in the floor. An increase in vagal tone can lead to nausea and vomiting and ultimately cardiac disorders, including asystole. These cases should be managed emergently.
- Volume discrepancies of the orbit can lead to enophthalmos or dystopia of the

globe. Early evaluation can be difficult because of edema and should be carefully monitored over a 2-week period as the edema subsides and the displacement becomes more obvious.

FIG 2 • The forced duction test.

- Delayed enophthalmos repair may be necessary even weeks after the injury if it is noted to be greater than 2 mm in an AP direction or is contributing to visual disturbances.

IMAGING

- CT scanning has revolutionized the diagnosis and treatment of orbital fractures.
- Coronal and sagittal reconstructions are most helpful for orbital floor fractures (**FIG 3**). They define the extent, size, and location of the injury, as well as associated injuries.
- 3D reconstructions can be helpful, especially in extensive injuries to outline

any other affected structures. This is very usual in nasoethmoidal orbital fractures, as well as associated zygomatic maxillary fractures.

- CT scan imaging distinguishes between a pure and an impure orbital floor blow-out fracture.

DIFFERENTIAL DIAGNOSIS

- Orbital roof fractures
- Medial orbit fractures
- Lateral orbital wall fractures
- Endocrine or systemic abnormalities affecting the orbit

NONOPERATIVE MANAGEMENT

- Significant controversy still remains regarding the operative vs nonoperative management of orbital floor fractures.
- As CT imaging technology has become more refined, a better evaluation and understanding of the injuries involved to the orbital floor permit better assessment and better selection of nonoperative candidates.
- Conservative management has become increasingly popular in recent years.
 - Some practitioners use a 1-cm defect in the floor as a cutoff for exploration as long as there is no evidence of herniation or clinical symptoms.
- After swelling and ecchymosis have resolved, if the patient is functionally intact, surgical correction may not be warranted. Delayed operative intervention after 2 or more weeks is also increasingly common among certain practitioners, especially ophthalmologists.
- Definite operative indications include significant enophthalmos, diplopia, ocular motility disturbances, and visual disturbances.

SURGICAL MANAGEMENT

Preoperative Planning

- A complete clinical assessment of the patient in particular of the orbit and periorbital structures.
- A good understanding of the mechanism of injury, of which structures are thought to be affected, and of the status of previous injuries to the area is vital.
- If any visual abnormalities are found or suspected, an ophthalmology consultation and a written assessment are crucial. If vision is normal, this should also be documented.

- CT scan images of the orbital floor fracture, including coronal and sagittal reconstruction from the axial images. The location and extent of the orbital floor fractures should be documented preoperatively.
- A forced duction test comparing the injured eye with the contralateral side.

FIG 3 • **A.** Coronal CT scan image showing left orbital floor blow-out including opacification of maxillary sinus. **B.** Sagittal CT image of orbital blow-out fracture. **C.** Axial CT image showing fracture of left orbital floor.

Orbital rim is intact. **D.** Bone image CT showing left orbital blow-out fracture.

- Tetracaine 0.5% drops may be required for local anesthesia.
- There are many types of materials that have been used that include, but are not limited to, autogenous bone graft, titanium mesh, porous polyethylene, porous polyethylene incorporated into a titanium mesh, gel foam, supramid cartilage, dermal fat grafts, etc.
- Our choice, at present, in a noncomplicated orbital blowout fracture, is to use porous polyethylene-coated titanium mesh.
- The thickness of the orbital implant is also important to keep in mind. There are thinner and thicker orbital implants, depending on the amount of the disruption of the floor and the need to elevate the globe to a certain level.
- The implant should be curved and fashioned to conform to the shape of the orbital floor. If the fracture extends to the medial or lateral walls, the implant can be curved to fit those extensions.

Positioning

- The patient is placed in a supine position.
- A shoulder roll is placed under both shoulders for gentle hyperextension of the neck. Both eyes and midfacial structures are exposed for evaluation and comparison.
- A corneal protective lens is placed on the affected side and usually on the contralateral side. The lens can be removed to check globe position and to perform ocular motility exams.

Approach

- A subconjunctival approach provides good exposure for the orbital floor.
- A subciliary incision is preferred for more extensive fractures of the floor.
- A canthotomy can be used with a subconjunctival incision for improved exposure.

TECHNIQUES

Video p2-c054

■ Dissection of the Orbital Floor

- Inject the lower eyelid, extending to the orbital rim, with lidocaine 1% with epinephrine 100 000.
- Perform a forced duction test and tactically evaluate globe pressure for future reference.
- The subconjunctival incision—at least 4 mm below the internal subciliary margin—is made with a Colorado Bovie tip set at 12 (**TECH FIG 1A,B**).
- A preseptal dissection is used to reach the orbital rim without penetrating the orbital septum or the fat pockets (**TECH FIG 1C,D**).
- The orbital rim periosteum is incised with cautery (**TECH FIG 1E**).

TECH FIG 1 • **A.** Incision is made in the conjunctiva with Bovie tip. **B.** Lateral view of cauterization of the conjunctiva. **C.** The septum is exposed. **D.** Lateral view of preseptal dissection. **E.** The septum is

dissected and the periosteum is incised with cautery.

F. The fracture is exposed and the periosteum elevated.

- The orbital periosteum is dissected with a periosteal elevator.
- Avoid further disruption of the delicate orbital floor.
- Visualize the infraorbital nerve and keep it out of harm's way.
- Expose the fracture and tease out the herniated contents and retrieve them back into the orbit (**TECH FIG 1F**).
- Continue the dissection posteriorly, measuring the distance from the orbital rim every so often, in order to note how close to the orbital apex the dissection has proceeded.
- Dissect posteriorly until the hard, bony ledge of the posterior orbit.
- The synthetic or bone implant must rest on this area to avoid prolapse into the maxillary antrum.

■ Implant Placement and Completion

- When dissection of the floor is complete, with visualization of the fracture, a decision is made about the reconstruction material.
- The defect is measured and the implant is tailored to fit the defect.
- The implant must sit on the posterior orbital ledge with extension to the orbital rim for fixation (**TECH FIG 2**).
- Once the implant is positioned, another forced duction exam is conducted to determine any restrictions in globe mobility.
- Both globes are then compared for symmetry.

TECH FIG 2 • A. Implant is positioned on the posterior orbital ridge and fixated to the orbital rim. **B.** Lateral view of implant in place.

- The reconstructed globe may be higher than the normal globe due to swelling.
- The surgical site is irrigated with normal saline and hemostasis obtained.
- Closure consists of approximating periosteal layers over the implant.
- The conjunctiva is sutured with interrupted, buried 5-0 catgut sutures.
 - Some surgeons do not repair the conjunctiva; however, closure may avoid the risk of entropion.
- Ophthalmic antibiotic ointment is applied to the conjunctiva and eyelid.

PEARLS AND PITFALLS

Implant placement

- Check the position of the implant to be certain it has not been displaced prior to closure.
- Conduct a forced duction test after placement of the implant.
- Fixation of the implant at the orbital rim will prevent implant dislodging.

- Close the periosteum over the implant to minimize palpability and decrease exposure or infection.

Side-to-side comparison

- Compare the final position of the operated globe with the contralateral side. The operative site will have a more elevated globe position due to swelling.
- Digital palpation of both globes before and after completion of surgery will determine that both globes are soft and within normal limits.

Postoperative care

- Check vision, globe pressure, and degree of pain control in the early postoperative period in the recovery room.

FIG 4 • **A.** Postoperative CT scan showing repair of orbital floor fracture (*arrow*). **B.** Sagittal CT image showing floor reconstruction with titanium plate in position. **C.** 3D CT image showing left orbital floor repair. **D.** Axial CT image showing repair of orbital floor with titanium plate.

POSTOPERATIVE CARE

- Preoperative IV antibiotics are given and maintained for 24 hours postoperatively.^{4,5}
- The position of the implant needs to be verified by CT in the postoperative period (**FIG 4**).

OUTCOMES

- The use and incorporation of alloplastic materials in the orbit have been shown to be of great benefit (**FIG 5**).
- These implant materials have better results than autogenous bone grafting.
 - They maintain their shape, thickness, and size.
 - Their porous nature helps vascular integration and decreases the chance of infection.³

COMPLICATIONS

- Acute complications include retrobulbar hematoma, sudden blindness, increased pain, and pressure in the globe.
- These all require immediate attention with release of sutures and a return to the operating room for further evaluation.⁶

FIG 5 • Six-month postoperative views. **A.** Patient looking forward. Note symmetry of globes without dystopia. **B.** Patient looking up, showing good extraocular muscle function. **C.** Patient looking down. He describes no diplopia. **D.** Patient from below showing no evidence of enophthalmos.

- Long-term complications include infection, migration or displacement of the implant, exposure and palpability of the implant, residual enophthalmos, diplopia, dystopia, and ocular motility problems.³
- With any of these complications, a CT scan should be conducted in the early postoperative period.

55 Correction of Lateral Orbital Wall Fractures

CHAPTER

Parit A. Patel

DEFINITION

- Of the seven bones that make up the orbit, the lateral orbit is composed mainly of the zygomatic bone.
- Fractures of the lateral orbit can result in expansion of the orbital volume with subsequent enophthalmos and orbital dystopia.
- Open reduction and internal fixation of the orbit restore the anatomy of the orbit and orbital volume. To restore the orbital volume successfully, the surgeon must have comprehensive understanding of the intricate anatomy of the orbit and surgical approaches to the orbit.

ANATOMY

- The orbit is a cone-shaped structure with a fixed volume.
- The seven bones that compromise the orbit include the sphenoid, maxilla, zygoma, frontal, ethmoid, lacrimal, and palatine.
- The contents of the orbit include the globe, extraocular muscles, cranial nerves II to VI, ophthalmic artery and other minor vessels, orbital fat, orbital septum, medial and lateral canthal tendons, check and suspensory ligaments, ciliary ganglion, lacrimal gland and sac, and nasolacrimal duct.
- The optic canal contains the optic nerve and ophthalmic artery. The superior orbital fissure contains cranial nerves III, IV, and VI. The inferior orbital fissure contains the infraorbital artery and vein and branches of the maxillary nerve.
- Orbital volume in the adult patient has been demonstrated to be $21.31 \pm 2.50 \text{ cm}^3$.¹
- Fractures of the lateral orbital wall can cause orbital volume expansion.

Fractures greater than 2.0 cm² can result in orbital expansion and clinically relevant enophthalmos.

- Fractures of the lateral orbital wall occur at the zygomatic sphenoid (ZS) suture, the greater wing of the sphenoid or the zygoma. The zygomatic portion of the orbit is the thickest bone of the orbit.
- Indications for treatment include clinically relevant expansion of the orbital volume with resulting enophthalmos and diplopia. Patients can also have blow-in fractures of the lateral orbit with associated proptosis.
- The lacrimal apparatus is important for tear production and drainage.
 - The lacrimal apparatus consists of the lacrimal gland, which is located in the superolateral aspect of the orbit and produces tears.
 - The lacrimal canaliculi, lacrimal sac, and nasolacrimal duct are important structures for draining tears into the nose (**FIG 1**).

PATHOGENESIS

- Lateral orbital fractures occur from significant force to the craniofacial skeleton due to trauma.
 - Impure fractures involve a fracture within both the orbit and the orbital rim.
 - Pure orbital fractures involve isolated fractures within the orbit.
 - The incidence of pure lateral orbital fractures is low, approximately 1% of all orbital fractures.²
- Lateral orbital fractures most commonly occur at the ZS suture and can be associated with zygomatic maxillary complex (ZMC) fractures.
- Fractures of the orbit can result in expansion of the orbital volume resulting in enophthalmos.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient usually presents with a history of significant facial trauma.
 - Associated signs and symptoms include periorbital pain, swelling, ecchymosis, dysesthesia, diplopia, and/or enophthalmos.

FIG 1 • Lacrimal apparatus.

- The patient can also have associated facial fractures that can be identified on physical examination with bony step-offs, gross facial asymmetries, and malocclusion.
- Enophthalmos can be identified using a Hertel exophthalmometer.
 - For every 1-cm³ volumetric increase in the orbital volume, enophthalmos increases by an increment of 0.89 mm.³
 - It can be difficult to assess enophthalmos in the acute setting because of periorbital swelling.
- The treating surgeon should be aware of surgical emergencies related to trauma to the orbit such as globe rupture, hyphema, entrapment, or a retrobulbar hematoma. In the setting of entrapment, there is restriction of movement of the globe.
- The clinical findings of a retrobulbar hematoma include severe ocular pain, visual acuity disturbance, and proptosis.

- There should be a low threshold for involving ophthalmology in situations of significant trauma to the periorbital region.
- Traumatic superior orbital fissure syndrome, although rare, can occur with lateral orbital wall fractures and is associated with ophthalmoplegia, proptosis, eyelid ptosis, a fixed and dilated pupil, and anesthesia in the ipsilateral ophthalmic branch of the trigeminal nerve. Orbital apex syndrome has a similar presentation; however, the patient additionally has visual loss from optic nerve injury.

IMAGING

- A CT scan of the face confirms clinical findings associated with facial fractures.
- The axial images will demonstrate the fracture of the lateral orbital wall and other related fractures, such as a ZMC fracture.
- The coronal images will demonstrate the size of the defect, which can be measured to assist in determining the indications for surgery.
- Sagittal images can help determine the posterior extent of the fracture and assist in sizing the implant or graft.

NONOPERATIVE MANAGEMENT

- If the fracture is less than 2.0 cm² and there are no signs of acute enophthalmos, the patient can be managed nonoperatively and monitored closely for development of enophthalmos and/or diplopia. There is approximately a 4- to 6-week window to treat the patient before the diplopia may require surgical correction.
- If the orbital fracture defect is marginal, the patient can be monitored until the swelling subsides to evaluate for enophthalmos.
- After resolution of swelling, if the patient has no signs or symptoms of enophthalmos or diplopia, surgery is not required.
- If there is a nondisplaced fracture of the zygomatic portion of the lateral orbital wall or at the ZS suture, the patient can be managed nonoperatively.
- Isolated fractures of the greater wing of the sphenoid, even with mild displacement, can be managed nonoperatively.

SURGICAL MANAGEMENT

- If the patient is stable, it is ideal to repair the orbital fracture in the first 24 to 48 hours.

- Beyond that time, there is maximal swelling that makes the operation and surgical approach more difficult.
- If the fracture is of marginal size and the patient does not have evidence of clinically relevant enophthalmos, the surgeon can wait 2 weeks to monitor and determine if surgery is indicated.
- Beyond 4 to 6 weeks, symptoms such as diplopia can be permanent and require strabismus surgery for correction.^{4,5}
- The objective of surgical intervention is to restore the anatomy of the orbit and the premorbid orbital volume. This prevents development of facial asymmetries related to enophthalmos or orbital dystopia. Furthermore, operative repair reduces the risk of developing strabismus and diplopia in the subacute phase or long term.
- Operative repair involves a surgical approach to the orbit through either a transconjunctival approach or a transcutaneous approach (ie, subciliary or midlid incision). Once in a subperiosteal plane, the periorbita is dissected free from the underlying bony orbit.
- Fractures of the lateral orbital wall occur most commonly at the ZS suture. The fracture can be comminuted and have an associated defect or be a linear fracture at the ZS suture or through the zygomatic bone.
- Depending on the extent of the fracture, the fracture can be repaired without bony fixation or with a titanium plate. If a sizeable defect is present, the lateral orbit can be reconstructed with an alloplastic orbital implant, mesh plate, or bone graft. If the fracture of the lateral orbit is associated with a ZMC fracture, the fracture at the ZS suture can be used to verify the reduction of the ZMC segment, with or without plate fixation.
- After open reduction and internal fixation, the lower lid is reconstructed appropriately to minimize the risk of ectropion, entropion, or lower lid malposition.
- All orbital fractures, including the lateral orbit, can be accessed through a transconjunctival approach to the orbit. A lateral cantholysis incision can be performed for additional access to the lateral orbital rim.

Preoperative Planning

- Risks and complications must be discussed with the patient and family. Risks include injury to the globe, postoperative enophthalmos, proptosis, orbital dystopia, persistent diplopia, visual acuity changes, postoperative entrapment, implant migration/infection, ectropion, entropion, and lower lid malposition.

- Orbital implants and an orbital/midface plating system should be available.
- Radiographic imaging should be available in the operating room for reference.

Positioning

- The patient is positioned supine with a shoulder roll in place.
- The operating table is positioned in Trendelenburg to maximize visualization of the orbit.

Approach

- The author recommends a transconjunctival approach to the orbit due to the ability to avoid external scars on the skin, ease of additional access to the lateral orbital rim with a lateral cantholysis from the same surgical field, and reduced rates of ectropion compared to other approaches.⁶

TECHNIQUES

■ Markings

- Needle-tip electrocautery is used to mark the conjunctiva 2 to 3 mm below the caudal aspect of the tarsal plate with a dotted line.
- The medial aspect of the marking should be lateral to the punctum.
- If a lateral cantholysis is needed, a marking is made at the lateral aspect of the palpebral fissure.
- Corneal shields are placed to protect the globe, and retraction sutures are placed in the lower eyelid at the gray line.
- With gentle traction, the lower lid is everted and pulled away from the globe.
- Local anesthetic, 50:50 mix of 1% lidocaine with epinephrine 1:200 000 and 0.5% Marcaine plain, is infiltrated into the lower lid conjunctiva and advanced deep to the orbital rim.

■ Exposure

- The conjunctiva and lower lid retractors are incised with needle-tip electrocautery on the pure-cut setting.

TECH FIG 1 • Surgical markings for the transconjunctival approach.

- With countertraction, the conjunctiva and lower lid retractors are pulled away from the lower lid (**TECH FIG 1**).
- The dissection continues caudally in the areolar plane between the lower lid retractors and the orbicularis oculi muscle (**TECH FIG 2A**).
- The dissection continues sharply in the preseptal plane to the arcus marginalis (**TECH FIG 2B**).
- The arcus marginalis is incised; in a subperiosteal plane, the periorbita is elevated from the orbital rim and orbital floor.
- A periosteal elevator is used to continue the dissection posterior into the orbit. The periorbita is dissected free from the fracture (**TECH FIG 2C**).
- Orbital retractors, including a Desmarres retractor (shown in **TECH FIG 2D**) and malleables are used for continued exposure of the orbital floor and lateral orbital wall.

- The dissection needs to continue into the orbit to identify the posterior ledge of the lateral orbital wall fracture (**TECH FIG 2D**).

TECH FIG 2 • A. Dissection between the lower lid conjunctiva and lower lid retractors. **B.** Anatomy of the arcus marginalis of the orbital rim and needle-tip Bovie incising the arcus marginalis. **C.** A periosteal elevator is used to dissect the periorbital free from the fracture

in a subperiosteal plane. **D.** Desmarres retractor is used in combination with malleables to retract the periorbital contents to visualize the lateral orbital wall fracture and posterior fracture edge at the level of the zygomatic sphenoid suture.

■ Fracture Repair

- If there is a comminuted fracture and a defect of the lateral orbital wall, a template is made of the defect, which is used to contour the orbital implant or mesh plate.
 - The implant can be fixated to the lateral orbital rim with a plate and or screw (**TECH FIG 3**).
- If the lateral orbital wall fracture is associated with a ZMC fracture, the fracture at the ZS suture can be used as a reference point for adequate reduction of the ZMC fracture.
 - A mini-titanium plate can be placed at the ZS suture.
- Ensure hemostasis and irrigate with saline.
- The globes should be assessed for symmetry and to rule out enophthalmos, proptosis, hyperglobus, or hypoglobus.
- Perform a forced duction test to verify that the implant is not entrapping tissue and restricting eye movement.
- The pupils should be evaluated throughout the case to verify that there is no compression on the optic nerve.

TECH FIG 3 • Orbital implant contoured and placed over the bony defect and secured in place with two screws at the orbital rim.

■ Lateral Cantholysis and Completion

- If the lateral orbital rim is involved, a lateral cantholysis can be performed for additional access.
- The lateral palpebral fissure is incised sharply down to the lateral canthal tendon.
 - The inferior limb of the tendon is incised sharply until the lower lid is dissected free and mobile (**TECH FIG 4A**).
- The periosteum is incised sharply, and with a periosteal elevator, the soft tissue is elevated from the lateral orbital rim (**TECH FIG 4B**).
 - If there is a fracture of the lateral orbital rim and displacement, the fracture fragments require reduction and fixation with plates and screws.
- If a lateral cantholysis is performed, the lateral canthal tendon will require reconstruction.

TECH FIG 4 • A. Lateral cantholysis incision at the lateral palpebral fissure and through the inferior limb of the lateral canthal tendon. **B.** Needle-tip electrocautery incising the periosteum of the lateral orbital rim. **C.** Reconstruction of the lateral canthal tendon with plating.

- A 4-0 Polydek suture is used to suture the lower lid to the superior limb of the lateral canthal tendon and periosteum on the inside of the lateral orbital rim (**TECH FIG 4C**).
- The conjunctival incision is closed with buried simple interrupted 6-0 fast gut suture.
- The corneal shields are removed and the globes irrigated with balanced salt solution.
- A Frost stitch is placed in the lower lid and secured to the forehead to support the lower lid postoperatively.
- In the postanesthesia care unit, visual acuity and the extraocular muscles are evaluated.

PEARLS AND PITFALLS

Physical findings

- It can be challenging to determine when to operate on marginal orbital wall defects.
- For defects larger than 2.0 cm², operative repair is indicated.

	■ For defects less than 2.0 cm², the patient can be monitored for signs of enophthalmos, and operative repair can be delayed for up to 4–6 weeks after injury.
Technique	■ The transconjunctival approach is the author's preferred technique due to the ability to avoid a scar on the face and the lower incidence of ectropion or lower lid malposition.⁶ ■ During the lower lid dissection, avoid entering the septum to minimize herniation of orbital fat into the operative field. The inferior oblique muscle can be injured if the septum is violated. ■ Perform a forced duction test after placement of the implant and examine the pupils periodically throughout the operation.
Postoperative care	■ Evaluate visual acuity and the extraocular muscles. ■ Support the lower lid with a Frost stitch or temporary tarsorrhaphy stitch to avoid lower lid malposition.

POSTOPERATIVE CARE

- Remove the Frost stitch on postoperative day 5.
- Ophthalmic bacitracin to the lateral cantholysis incision if performed.
- Lower lid and scar massage can be started at 4 weeks as needed.

OUTCOMES

- The incidence of postoperative enophthalmos has been reported to be as high as 27.5% and the incidence of postoperative diplopia, 42.5%. Operative repair before 2 weeks reduces the incidence of postoperative diplopia.⁷
- The incidence of infraorbital nerve dysfunction or hyperesthesia has been noted in 55% of patients postoperatively.⁷
- The highest rates of lower lid ectropion and revision surgery are associated with the subciliary approach (19.9%). Moreover, the lower lid scar was noticeable and found to have an unacceptable result in 43% of patients.⁶
- Of the three surgical approaches to the orbit, the subtarsal incision has the second highest complication rate and the transconjunctival approach has the lowest.^{6,8}
- Hardware extrusion, malposition, or infections related to orbital fractures are exceedingly rare.⁷

COMPLICATIONS

- Persistent diplopia after surgical repair can occur and may require further

revision surgery.⁹

- Postoperative enophthalmos can occur due to expansion of orbital volume, prolapse of tissue into the orbital defect, and fat atrophy. This situation requires revision surgery if clinically evident. Orbital dystopia can also occur postoperatively if there is inadequate reduction of the lateral orbital wall fracture when associated with a ZMC fracture.⁷
- Infraorbital nerve dysesthesia can occur from traumatic injury secondary to the fracture or by iatrogenic means.⁷

56 Medial Orbital Wall Fractures

CHAPTER

Brad M. Gandolfi, Reena Bakshi, and Reza Jarrahy

DEFINITION

- Medial orbital wall fractures are traumatic injuries of the orbit that compromise the integrity of the medial orbital wall.
- These typically occur at the *lamina papyracea*, the thin central portion of the medial orbital wall, and may involve herniation of periorbital soft tissues into the adjacent ethmoid sinuses.

ANATOMY

- The anatomy of the orbit represents a complex interplay between bony structures and their associated soft tissues.^{1–5}

Bony Anatomy

- The overall configuration of the bony orbit is pyramidal, with walls that are curvilinear.
 - The height of the orbit averages 35 mm, with an average width of 40 mm.
 - The distance from the midpoint of the inferior orbital rim to the orbital apex measures approximately 45 mm.
- The medial orbital wall is the thinnest wall of the orbit. It is primarily composed of the lacrimal bone anteriorly and the orbital plate of the ethmoid bone posteriorly.
 - These structures are closely related to the orbital processes of the frontal, sphenoid, maxillary, and palatine bones.
- Ethmoid bone:
 - The orbital plate of the ethmoid bone accounts for the largest portion of the medial orbit wall. It is also the thinnest portion of bony orbit.

- The thin curved central area of this bone is referred to as the lamina papyracea. Due to its thin nature, most medial orbital wall fractures occur through the lamina papyracea, as opposed to the thicker anterior and posterior portions of the medial orbit.
- An extensive labyrinthine network of honeycomblike pneumatized air cells forms the ethmoid sinus medial to the lamina (**FIG 1A**).
- Frontal bone:
 - The orbital process of the frontal bone articulates with the ethmoid bone in the superior and posterior portion of the bony orbit.
 - The frontal bone is thicker than the lamina papyracea, providing protection to adjacent intracranial structures.
 - The roof and medial wall of the orbit meet at the frontoethmoidal suture. The anterior and posterior ethmoidal arteries, branches of the ophthalmic artery, enter the orbit through their respective foramina in the frontoethmoidal suture (**FIG 1B**).
 - The anterior ethmoid foramen is located approximately 15 mm posterior to the medial orbital rim and the posterior foramen is located approximately 10 mm further posteriorly.
 - Disruption of the anterior and/or posterior ethmoid arteries contributes to hemorrhage in the setting of medial orbital wall fractures.
- Lacrimal bone:
 - The lacrimal bone is related to the anterior and inferior aspects of the ethmoid bone.

FIG 1 • A. Skull model demonstrating the thin nature of the lamina papyracea and the network of ethmoid air

cells lying medial to the orbit. **B.** The anterior and posterior ethmoid foramen are located on the frontoethmoidal suture.

- The central portion of the lacrimal bone is characterized by a depression—the lacrimal fossa—that contains the lacrimal sac. This central recessed portion of the lacrimal bone is surrounded by the anterior and posterior lacrimal crests.
- The medial canthal tendon inserts onto the anterior and posterior lacrimal crests.
- Sphenoid bone:
 - The sphenoid bone abuts the posterior edge of the orbital plate of the ethmoid bone.
 - It delineates the most posterior portion of the medial orbital wall and defines the optic foramen in the orbital apex.

Soft Tissue Anatomy

- Knowledge of the soft tissue anatomy of the medial orbit is necessary to safely and effectively manage medial orbital wall fractures without inadvertently injuring surrounding critical structures.
- Lacrimal caruncle and plica semilunaris (semilunar fold):
 - The lacrimal caruncle sits at the medial corner of the eye between the upper and lower eyelids, in close proximity to the medial canthal tendon. It is a fleshy nodule that contains sebaceous and sweat glands that help maintain normal ocular physiology.
 - It serves as a useful anatomical landmark for surgical approaches to the bony orbit.
 - The plica semilunaris is a fold of conjunctiva that sits between the caruncle and medial sclera. The plica assists in normal tear function and facilitates movement of the globe (**FIG 2A**).
- Medial canthal tendon:
 - The medial canthal tendon is associated with the orbicularis oculi muscle and defines the shape and position of the medial poles of the upper and lower eyelids.

FIG 2 • A. The caruncle (*blue arrow*) and plica semilunaris (*red arrow*) help regulate normal ocular physiology and globe movement. The puncta on the upper and lower lids (*circled*) drain the eye. **B.** Sagittal section at the level of the attachment of the medial canthal tendon to the lacrimal crest. The medial canthal tendon splits into anterior and posterior components, enveloping the lacrimal sac and canaliculi. **C.** Relationship between the caruncle (C), puncta (P), the lacrimal apparatus, and the plica semilunaris. The medial canthal tendon has been removed to show the

anatomy. The lacrimal fossa (outlined in **D**) houses the lacrimal sac, which drains through the nasolacrimal duct (**E**).

- The tendon originates from fascial extensions of the upper and lower tarsal plates and divides into three limbs that insert in a fanlike fashion onto the medial orbital wall.
- Disruption of the medial canthal tendon from its bony insertions can have a significant deleterious effect on ocular function and aesthetics (**FIG 2B**).
- Anterior limb:
 - The anterior limb of the medial canthal tendon inserts onto the anterior lacrimal crest and forms the bulk of the tendon.
 - The pretarsal, preseptal, and orbital orbicularis fibers insert onto the anterior limb.
- Superior limb: The superior limb of the medial canthus extends over the lacrimal sac and covers its anterior and superior portions.
- Posterior limb:
 - The posterior limb of the medial canthal tendon inserts onto the posterior lacrimal crest.
 - Although not as robust as the anterior limb, its posterior vector is integral in maintaining apposition of the upper and lower lids to the globe.
 - It is closely related to the Horner muscle, a slip of the lacrimal portion of the

orbicularis oculi muscle, which contributes to regulation of normal lacrimal flow.

■ Lacrimal system:

- Puncti: The superior and inferior puncti serve as the primary site of drainage for the eye. They are located approximately 5 to 7 mm lateral to the medial canthal angle (circled in **FIG 2A**). The upper lid punctum is usually positioned 1 to 2 mm more medial than the lower lid punctum. The majority of tear volume is drained through the lower lid.
- Canaliculi: The canaliculi connect the puncti to the lacrimal sac. The ampullae are the vertical components of the canaliculi and are located directly beneath the puncti. The ampullae measure 2 mm in length on average. The canaliculi then turn sharply and extend medially along the border of the eyelid. They merge into a single duct before entering the lacrimal sac (**FIG 2C**).
- Lacrimal sac: The lacrimal sac is located within the lacrimal canal of the lacrimal bone between the anterior and posterior lacrimal crests and the anterior and posterior limbs of the medial canthal tendon (**FIG 2C–E**). It is partially covered by the superior limb of the medial canthal tendon and extends 5 mm superior to this structure. The sac continues into the nasolacrimal duct at the base of the lacrimal fossa, which continues through an intraosseous tunnel to drain into the nose lateral to the inferior nasal turbinate through the inferior meatus.
- Medial rectus muscle: The medial rectus muscle originates at the annular tendon, a fibrous ring surrounding the optic canal at the orbital apex. It inserts onto the medial surface of the globe and is innervated by the inferior division of the oculomotor nerve. Its primary function is to medially adduct the eyeball. Due to its location in the medial orbit, the medial rectus muscle is vulnerable to entrapment in a blow-out fracture through the medial orbital wall.

PATHOGENESIS

- Medial orbital fractures typically result from direct blunt trauma to the orbit. Mechanical energy transmitted to the medial orbital wall and/or hydraulic retropulsion of the globe into the orbit can cause structural damage to the medial orbital wall, particularly at the thin lamina papyracea.⁶
- Fractures of the medial orbital wall can play a protective role: absorption of energy by bone limits energy transfer to the orbital soft tissues, decreasing the

likelihood of traumatic globe rupture.

NATURAL HISTORY AND PHYSICAL FINDINGS

- Symptoms of medial orbital wall fractures include pain with extraocular muscle movement, ecchymoses, and periorbital edema. Physical examination findings include diplopia, enophthalmos, crepitus, visible or palpable medial orbital rim irregularities, and telecanthus.
- Cerebrospinal fluid leakage and epistaxis can also be seen in severe orbital injuries that involve adjacent intracranial or nasal structures.
- A formal ophthalmological evaluation should be performed to assess baseline ocular function. The ophthalmologist should document a complete examination, including assessment of visual acuity, pupillary reactivity, anterior and posterior ocular chambers, and extraocular muscle function. In the setting of medial rectus muscle entrapment, restriction of extraocular movements may be observed.

IMAGING

- Plain film radiography is of limited value in the assessment of medial wall fractures, although disruption of the medial orbit and opacification of the ethmoid sinus can sometimes be detected on x-ray.
- Fine-cut axial CT scan with multiplanar reconstruction has great sensitivity and specificity for identifying medial orbital wall fractures. Two-dimensional axial and coronal views can accurately image the disruption of the medial orbital wall and demonstrate herniation of periorbital soft tissues into the ethmoid sinuses (**FIG 3A,B**).
- Three-dimensional (3D) reconstructions of orbital CT scans are generally not helpful in diagnosing medial orbital wall fractures. The algorithms used by most 3D imaging software programs currently do not provide adequately detailed renderings of the surface anatomy of the thin curved medial orbital wall⁷ (**FIG 3C,D**).

FIG 3 • Axial (**A**) and coronal (**B**) computed tomography (CT) imaging of the orbit demonstrating fracture of the (*right*) medial orbital wall with herniation of periorbital soft tissues into the ethmoid sinus (*circled*). **C,D**. 3D rendering of the same injury does not provide a detailed anatomic picture.

DIFFERENTIAL DIAGNOSIS

- Direct trauma to the eye resulting in medial orbital wall fractures can also cause injury to other parts of the orbit. Orbital floor fractures and, more rarely, orbital roof fractures can present with edema, ecchymosis, enophthalmos, and diplopia.
- Injuries to surrounding structures may also present in similar fashion, including fractures of the nasal bones, anterior cranial base, frontal sinus, and naso-orbitoethmoidal (NOE) complex.
- The pain and ophthalmoplegia of superior orbital fissure syndrome can mimic the discomfort and restriction of gaze associated with medial rectus entrapment.

NONOPERATIVE MANAGEMENT

- In some circumstances, medial orbital wall fractures can be managed nonoperatively. In the setting of a small defect without diplopia, significant enophthalmos, or medial rectus entrapment, observation is a reasonable option.
- Principles of nonoperative management include head elevation, application of ice cold compresses, and minimizing increased intraorbital pressure by avoiding nose blowing and other Valsalva maneuvers for 4 to 6 weeks following the injury.

SURGICAL MANAGEMENT

- Open repair of medial orbital wall fractures is indicated in the setting of large bony defects, early or persistent enophthalmos with associated diplopia, or medial rectus muscle entrapment.
- The goals of surgical management are release of any entrapped orbital soft tissues, replacement of periorbital into the bony orbit, restoration of orbital domain, and correction of enophthalmos and diplopia.
- A variety of approaches to the medial orbit have been described, each with its specific advantages and disadvantages^{6,8} (Table 1). Similarly, there are a variety of materials that may be used to repair the medial wall defect⁹ (Table 2). These are discussed in detail elsewhere in this text. The authors' preferred technique is a transcaruncular approach to the medial orbit with autologous split calvarial bone graft repair. Autologous bone harvest adds little additional time, cost, or morbidity to the operation. In skilled hands, harvesting autologous bone should be quick, straightforward, safe, and cost efficient.¹⁰
- Split calvarial bone grafts are taken from the parietal region. Here, the diploic space is well formed and the calvarial bone is consistently thick, particularly in the central 8 × 10 cm of the parietal bone.

Preoperative Planning

- The patient should be thoroughly informed of risks, benefits, and expected outcomes of the procedure, including the possibility of persistent diplopia, postoperative enophthalmos, or loss of vision.
- Preoperative CT scans should be used to plan the surgical intervention and should be available for review during the procedure.
- Surgery should be performed after resolution of acute postinjury inflammation and edema. Early intervention has been previously recommended, but recent

evidence has shown that delayed repair of orbital fractures can be equally effective.¹¹

- Fine ophthalmological instruments are helpful in manipulating the soft tissues of the eyelids and medial orbit.

Positioning

- The patient is placed on the operating room table in the supine position. A shoulder roll is placed to obtain slight neck extension. This is deferred if the patient is under cervical spine precautions.

Table 1 Approaches to the Medial Orbital Wal

Approach	Advantage	Disadvantage	Major Indication
Coronal	Full exposure of the superior and medial orbit	Higher level of invasiveness; extensive external scar; risk to temporal nerve; significant postoperative edema	Complex fractures involving orbit and surrounding structures; NOE fractures
Medial transcutaneous (Lynch incision)	Direct and wide exposure of entire medial orbital wall	Risk of injury to medial canthal tendon and lacrimal structures	Resection of large lesions involving the nose and ethmoid sinus
Transcaruncular	No skin incision	Limited access to larger defects involving the orbital floor	Isolated medial orbital injuries
Transconjunctival with transcaruncular extension	Wide exposure of the orbital floor and medial orbital wall	Larger incision with greater risk of conjunctival scarring and ectropion/ectropion	Orbital wall injuries involving both the floor and the medial orbital wall
Transnasal endoscopic	No incisions	Requires endoscopic equipment and	Small to medium-sized isolated medial orbital

		expertise; potentially difficult reduction of soft tissues; limited reconstructive options; no direct access to orbit	fractures
--	--	---	-----------

Table 2 Comparison of Commonly Used Reconstructive Materials for Orbital Wall Repair

Implant Type	Advantages	Disadvantages
Split autologous bone graft (calvarium, rib, iliac)	Readily available; osteoconductive; minimal scarring in revision setting; radiopaque; most cost-effective	Unpredictable resorption; added donor site morbidity; not advisable with intracranial injury or thin bones (eg, elderly patients)
Porous polyethylene	Moldable; soft tissue ingrowth stabilizes position	Difficult to remove (dense adhesions to orbital soft tissues); possible higher infection rate; high cost
Titanium	Moldable; easy to use; low infection rate	Difficult to remove (dense adhesions to orbital soft tissues); high cost; unclear safety profile in children
Absorbable plates	Easily moldable; minimal infection rate; low adhesion profile in revision setting	Cost; less applicable to large defects
Custom 3D-printed implant	Custom design for most accurate fit over defect	Cost; requires presurgical virtual surgical planning session; infection risk unclear; long-term outcomes unclear

TECHNIQUES

■ Medial Orbit Exposure

- The procedure is performed under general endotracheal anesthesia via an oral RAE tube secured in the facial midline.
- A dose of intravenous cephalosporin antibiotic (cefazolin) is given following the induction of anesthesia and prior to incision.
- In anticipation of cranial bone graft harvest, a planned zigzag incision is marked with ink behind the temporal hairline between the midline of the skull and the temporal crest. This location avoids the sagittal sinus in the midline and the temporalis muscle laterally during bone graft acquisition. The hair overlying this area is clipped (**TECH FIG 1A**).
- The scalp and face are prepped in standard fashion, and the head is wrapped with sterile surgical drapes. A corneal protector may be placed for protection of the surface of the globe.
- 0.25% bupivacaine with 1:200 000 dilute epinephrine is used to infiltrate the conjunctiva, plica semilunaris, and caruncle.
- The upper and lower eyelids are gently retracted and a needlepoint cautery tip is used to incise the conjunctiva and bisect the caruncle (**TECH FIG 1B**). The initial incision is 15 mm in length. It can be extended in crescentic fashion either superiorly or inferiorly for increased exposure.
- Retractors are repositioned under the medial and lateral cut edges of the caruncle to expose the medial orbital septum. Using cautery, sharp scissor dissection, Freer elevator, or a cotton-tipped applicator, dissection proceeds in a preseptal plane toward the medial orbital wall (**TECH FIG 1C**).

TECH FIG 1 • A. Positioning the incision for cranial bone graft harvest between the midline and temporal crest provides direct access to the thick parietal bone while avoiding the midline sagittal sinus and the temporalis muscle. **B.** The caruncle is bisected and conjunctiva incised and retracted. Cautery and sharp or blunt dissection are used to perform preseptal dissection to the medial orbital wall as seen here. **C.** The dissection continues posterior to the posterior lacrimal crest along the bone or whatever remnants of bone exist. **D.** The dissection extends through the caruncle in a subperiosteal plane if available. The

dissection is lateral to the lacrimal apparatus and medial to the orbital fat pads. **E.** The entire defect is exposed in a subperiosteal plane, and stable surrounding bone is identified for anticipated bone graft placement.

- Once the medial orbital wall is exposed, the posterior lacrimal crest must be identified, and dissection must proceed posteriorly to avoid injury to the medial canthal tendon (**TECH FIG 1D**).
- Needlepoint cautery is used to incise the periosteum posterior to the lacrimal crest. A Freer elevator is used to obtain wide subperiosteal elevation around the entire circumference of the bony defect (**TECH FIG 1E**).
- During the dissection, all orbital contents should be reduced back into the orbit, including any entrapped tissues such as the medial rectus muscle. Malleable retractors are effective in retaining the periorbita within the bony orbit while periosteal elevators are used to elevate the periosteum.
- If the anterior or posterior ethmoid arteries are identified during the dissection and found to be intact, they should be carefully cauterized using a bipolar cautery device.
- Dissection should proceed until stable bone to support a bone graft is identified around the entire periphery of the defect.
- After the medial wall defect is completely exposed, a template can be made to guide sizing of the bone graft or implant to be used in the repair. A 1- × 3-cm cotton sponge is placed over the medial wall defect and used to keep the orbital contents within the orbit while the bone graft is procured.

■ Graft Harvest

- 0.25% bupivacaine with 1:200 000 dilute epinephrine is infiltrated into the zigzag scalp incision site.
- The scalp is incised with a beveled blade so that the plane of dissection lies parallel to the hair follicles. The size of the incision varies according to the size of bone graft needed.
- Once the dermis and subcutaneous tissues are sharply incised, electrocautery is used to open the galea. Care is taken to avoid cauterizing the dermis and

hair follicles.

- Blunt subgaleal dissection with a subperiosteal elevator is performed to mobilize the overlying scalp. The loose areolar subgaleal plane can be dissected rapidly and the scalp retracted to expose the underlying parietal bone with its adherent periosteum.
- Based on the size of the medial wall defect and template, the margins of the desired bone graft are marked by incising the periosteum with needle tip cautery. A graft measuring 2×3 cm to 3×4 cm is usually adequate. The graft should be designed to allow for circumferential overlap with the intact medial orbital wall surrounding the fracture site.
- A sharp curved osteotome and heavy mallet are used to harvest the graft. The bone graft is harvested in a superficial plane above the level of the deep diploe.
- The depth of the osteotome must be precisely controlled at all times. Avoid driving the osteotome through the inner table and injuring the intracranial structures.
- The graft is harvested from an anterior to posterior direction. The osteotome is used to shave the bone graft from the outer table of the cranium by continuously moving between the anterior and lateral edges of the graft and staying superficial. The graft is elevated with its overlying pericranium, which serves to keep the graft intact.
- If the bone graft begins to flake or fracture due to excessively superficial positioning of the osteotome, it should be reoriented to engage a deeper layer of the outer table. Similarly, if there is excessive bleeding from trauma to the deep diploic space, the osteotome should be redirected to a more superficial plane.
- When an adequate length of bone graft has been raised, the osteotome is directed superficially to release the graft from the skull. Sharp scissors are used to cut the adherent posterior periosteum, and the graft is delivered from under the scalp flaps.
- Hemostasis of the skull donor site and scalp is obtained using bone wax and cautery as needed.
- The galea is closed with interrupted buried 3-0 Monocryl suture. The superficial layer of the scalp is closed with a running locking 4-0 plain catgut suture.
- (Note: An alternative technique that yields a full-thickness outer table bone

graft can be employed as well. Using a high-speed cutting bur, the margins of the bone graft can be drilled down to the level of the diploic space. The graft can then be removed from the underlying diploe using the osteotome or a reciprocating saw, again with great attention to the depth of these instruments. This full-thickness graft is more stiff and brittle than the partial-thickness outer table shave and may be less amenable to shaping and contouring for precise coverage of the medial wall defect.)

■ Fracture Repair

- Once the graft is harvested, attention is turned to the orbit to complete the repair of the medial wall fracture. Prior to placement in the orbit, the bone graft can be cut and contoured as needed *ex vivo* using bone-cutting instruments and Tessier bone-bending forceps.
- The cotton patty that was previously placed in the orbit is removed as a malleable retractor is again placed to retract the orbital contents laterally and expose the medial wall fracture.
- The bone graft is placed over the defect. If appropriately sized and designed, the graft should rest on the surrounding intact bone with stability, and there should be no need for fixation (**TECH FIG 2**).
 - (Note: If the medial wall is severely comminuted and there is a paucity of stable bone on which the graft can rest, it can be rigidly fixed to stable anterior bone using 1.3-mm titanium miniplates and screws. In such cases, the fixation plate can be screwed to the bone graft *ex vivo* and the graft can then be placed into the orbit in the desired position. It can then be secured to the anterior orbit. Great care must be taken to avoid injury to the medial canthal tendon and the lacrimal apparatus if rigid fixation is implemented.)
- Once the graft is in place, the retractors are removed and the soft tissues are released.
- A forced duction of the eye is performed by gently grasping the medial and lateral sclera with toothed ophthalmic forceps and moving the globe in all directions. Free motion of the globe confirms that no entrapment of the orbital soft tissues has taken place during positioning of the bone graft.
- The caruncular incision is closed with buried interrupted 6-0 plain catgut sutures, using the bisected caruncle as a landmark for accurate wound alignment.

- If there is significant soft tissue edema of the orbital tissues causing exophthalmos, and postoperative corneal exposure is a concern, a temporary lateral tarsorrhaphy suture is placed using 5-0 silk suture.

TECH FIG 2 • The bone graft is placed over the defect. The surrounding intact bone supports the graft.

PEARLS AND PITFALLS

Corneal protection

- Once the patient is anesthetized, communicate with the anesthesiologist regarding corneal protection. Many anesthesiologists like to place lubricating ointment on the surface of the globe to prevent intraoperative corneal desiccation and may do so without informing the surgeon. However, the presence of this thick gelatinous ointment can complicate the initial caruncular incision and dissection. A corneal protector avoids this issue.

Incision placement

- Care must be taken to identify the puncta before incision and to preserve them throughout the dissection. Careless manipulation of the eyelid can result in inadvertent injury to the puncta requiring additional reconstruction.

Enophthalmos

- Perform a physical examination immediately prior to beginning

	surgery with the patient in the supine position. Note the degree of enophthalmos by examining the patient from superior and inferior perspectives, and use these observations as indices to judge your correction once the bone graft is placed.
Anesthesia	■ Local anesthesia may be used to infiltrate the periorbital soft tissues prior to surgery. Epinephrine injected into the conjunctiva may cause dilation of the pupil and lower intraocular pressure.
Cautery	■ When using cautery within the orbit, be attentive to the current settings. Thermal energy from the cautery device can dissipate throughout the orbit and damage the periorbital soft tissues. Within the orbit, use bipolar cautery to limit inadvertent heat transfer.
Soft tissue dissection	■ Once in the preseptal plane, a back-and-forth sweeping motion with a cotton-tipped applicator is very safe and effective in rapidly dissecting the soft tissues down to the level of the orbital wall.
Anatomic landmarks	■ The vertical level of the anterior and posterior ethmoidal arteries within the orbit approximates the level of the cranial base. Be aware of the location of these anatomic landmarks to identify any potential involvement of intracranial structures in the medial orbital injury.
Orbital safe zone	■ A medial orbital safe zone of dissection exists up to 30 mm posterior to the orbital rim. Dissection in this zone can be performed without fear of injury to structures that occupy the orbital apex.
Pressure on the globe	■ Pressure on the globe may elicit an oculocardiac reflex with resultant bradycardia and hypotension. Alert the anesthesiologist during the surgery if you need to place pressure on the globe and be prepared to release your retraction if there are any physiological consequences to your manipulation.
Bone grafts	■ In complex fractures that involve extensive injury to the ethmoid air cells, multiple bone grafts may be stacked to restore integrity to the medial orbital wall.
Intraoperative navigation	■ Intraoperative navigation may assist in defining the medial orbital defect, confirming accurate placement of the bone graft, and avoiding injury to critical structures in the orbital apex (FIG 4).

FIG 4 • Intraoperative navigation systems may help avoid injury to critical structures and confirm accurate graft placement.

POSTOPERATIVE CARE

- Cold compresses are placed on the eye continuously for the first 3 to 5 days following surgery; the first compresses are applied before the patient leaves the operating room. The patient's head is elevated during this time as well.
- Postoperative visual acuity examinations should be performed every 1 to 2 hours for the first 24 hours postoperatively. Even if the eyelids are swollen shut following surgery, light perception adequately confirms afferent optic nerve function.
- If a temporary tarsorrhaphy stitch is placed at the end of the operation, it is removed on the first postoperative day if there is no evidence of actual or threatened corneal exposure.

- The patient is counseled to not blow his/her nose for 6 weeks and to sneeze with an open mouth during that time to minimize elevation of intraocular pressure.

OUTCOMES

- If the medial orbital wall defect is well visualized and the bone graft is appropriately positioned, success rates are high, as defined by correction of enophthalmos, resolution of diplopia, release of any entrapped soft tissues, and preservation of the function and aesthetics of the medial canthal tendon and upper and lower eyelids.

COMPLICATIONS

- When using this technique in the treatment of medial orbital wall fractures, complications are rare. When they do occur, however, they can be severe.
- Blindness is the most severe and devastating complication that can result from any intraorbital surgery. Patients must be counseled that this is a possible outcome of surgery, albeit extremely rare. Knowledge of the surgical anatomy of the orbit and avoidance of aggressive surgical dissection in the orbital apex mitigate the chances of vision loss.
- Persistent or new-onset diplopia may be seen in the postoperative period. This can be due to iatrogenic injury to the rectus muscles, postoperative muscle fibrosis, or undiagnosed muscle injury sustained at the time of original trauma. True medial rectus entrapment warrants urgent intervention and release to prevent ischemia of the muscle and permanent muscle damage.
- Corneal injury, either due to iatrogenic abrasion or perioperative exposure, can lead to visual deficits.
- Conjunctival scarring can lead to cicatricial entropion or ectropion, both of which can be very difficult to correct.
- Injury to the medial canthal tendon during fracture repair may result in telecanthus that may require medial canthopexy repair.
- With any orbital surgery, and particularly with procedures that involve exposure of nonvascularized bone graft to sinus flora, the risk of infection is not insignificant.

57 Correction of Orbital Roof Fractures

CHAPTER

Samita S. Goyal and James Jensen

DEFINITION

- Orbital roof fractures may occur in isolation but more often are a part of a larger pattern of traumatic injury.
- Classification¹:
 - Nondisplaced fractures
 - Isolated blow-in fractures
 - Orbital roof displaced inferiorly into orbit
 - No involvement of supraorbital rim or frontal sinus
 - Due to sudden increased intracranial pressure and shift of the cranium and intracranial contents; usually associated with severe brain injury
 - Leads to decreased volume of orbit and possible displacement of globe
 - Most likely injury type to require surgical intervention
 - Isolated blow-up (blow-out) fractures
 - Orbital roof displaced superiorly into anterior cranial fossa
 - No involvement of supraorbital rim
 - Due to increase in intraorbital pressure, hydraulic force, or shear strain
 - Leads to increased volume of orbit
 - Roof (blow up or blow in) and supraorbital rim

ANATOMY

- The orbital roof is a thin, slightly concave bone that separates orbital contents and the anterior cranial fossa.
- Includes the lateral extent of the floor of the frontal sinus
- Consists primarily of the orbital plate of the frontal bone; lesser (posterior)

contribution is from the greater and lesser wings of the sphenoid bone (**FIG 1**)

- The endocranial surface is characterized by multiple ridges and thin bones that may have a role in fracture patterns.
- The orbital surface is smooth and thin and includes the lacrimal fossa, a depression in the anterolateral orbital roof that contains the lacrimal gland.
- The supraorbital rim confers rigidity to the superior orbit.
- Structures in proximity to the orbital roof include the following:
 - Orbital septum
 - Lacrimal gland
 - Superior rectus muscle
 - Superior oblique muscle
 - Levator palpebrae superioris muscle
 - Supraorbital and supratrochlear nerves
 - Superior division of the oculomotor nerve
 - Globe

PATHOGENESIS

- Orbital roof fractures make up 1% to 9% of all facial fractures.
- Likely to have craniofacial, intracranial, ophthalmic, or other bodily injuries (isolated orbital roof fractures in adults are rare)
- In adults, most commonly seen in men 20 to 40 years of age (89%–93%).²
- More commonly seen in pediatric patients under 7 years of age³:
 - Children older than 7 years are more likely to sustain orbital floor fractures.
 - Young children have a high cranial:orbital ratio, incompletely pneumatized frontal sinus makes less likely shock absorption than in older children/adults; in high-energy impact situations, energy is more efficiently transmitted through the orbital roof.
- Most commonly due to high-energy impact injuries to the face
- Etiology
 - Mechanical vapor compression (MVC) (high energy): higher risk of comminution³
 - Fall: more likely linear pattern³
 - Assault
- Commonly seen at the junction of middle and medial thirds of orbital roof

FIG 1 • Submental view of orbital skeletal anatomy demonstrating that the majority of the roof is frontal bone.

- Concomitant facial fractures²:
 - Frontal sinus (95%)
 - Orbital rims (60%)
 - Naso-orbital-ethmoidal region (33%)
 - Orbital wall fractures (33%)
 - Le Fort fractures (27%)
 - Also associated with fractures of the cribriform plate, lateral orbital wall, squamous portion of the temporal bone, and planum sphenoidale
- Concomitant soft tissue injuries: 25% of all fractures involving orbit have ocular injuries.⁴

NATURAL HISTORY

- In pediatric fractures, orbital roof fractures may develop into growing fractures³:
- Growing skull fractures—cranial fracture combined with dural tear and brain

herniation in a growing brain—can lead to progression of osseous defect with growth.⁵

- Frontal and parietal regions more commonly affected
- More likely to be seen in children less than 3 years of age (period of rapid brain growth)
- Suspect risk for development into growing fracture if imaging suggests herniation of intracranial contents into orbital region
- Isolated orbital roof “blow-in” fractures may autoreduce with resolution of cerebral edema if the dura is reasonably intact and apposed to the bone.⁶

PATIENT HISTORY AND PHYSICAL FINDINGS

- History
 - Blunt or penetrating facial trauma
 - Diplopia
 - Eye pain
 - Diminished visual acuity
 - Blindness
- Physical findings
 - Superior orbital rim contour deformity
 - Periorbital or conjunctival ecchymosis and edema
 - Epiphora
 - Hypesthesia/paresthesia of supraorbital and/or supratrochlear nerves
 - Orbital emphysema
 - Soft tissue lacerations
 - Enophthalmos/hyperglobus (blow-out fracture)
 - Exophthalmos/hypoglobus/proptosis (blow-in fracture)
 - Extraocular muscle entrapment or imbalance (superior rectus muscle) with disconjugate gaze
 - Blepharoptosis due to injury to the levator palpebrae
 - Afferent pupillary defect
- Neurological comorbidity
 - Dural injury with cerebrospinal fluid (CSF) leak (clear rhinorrhea)
 - Intracranial hemorrhage
 - Pneumocephalus (implies dural disruption)
 - Meningitis
 - Brain injury
- Ophthalmic comorbidity

- Optic nerve compression or laceration
- Detached retina
- Retrobulbar hematoma
- Globe rupture
- Ptosis or lagophthalmos
- Intraorbital foreign bodies
- Extraocular motor nerve palsies
- Orbital encephalocele/intrusion

IMAGING

- Standard of care imaging modality: thin-slice (1 mm) computed tomography (CT) scan¹:
 - Axial, coronal, and sagittal views essential to provide complete assessment of degree of displacement and impact on surrounding structure.
 - 3D views not essential, but can be helpful in badly displaced/comminuted fractures, especially if utilizing a limited access approach
 - Advantages: rapid, available, provides ability to assess intracranial content/injury
- Magnetic resonance imaging (MRI): impractical as it is an insensitive exam of the bone and some foreign objects; contraindicated in situations where metallic foreign objects (bullet fragments) may be present in soft tissues (**FIG 2**).

FIG 2 • Comminuted orbital roof/frontal sinus fracture with rim involvement in a 19-year-old following blunt force trauma (baseball). The patient had a ptotic upper lid secondary to inferior displacement of orbital roof (indicated by leader in **(A)**). **B.** 3D CT scan demonstrating the comminuted fracture. **C.** 3D CT bird's eye view of the fracture. **D.** Soft tissue envelope demonstrating the depressed eyebrow associated with the fracture.

NONOPERATIVE MANAGEMENT

- Conservative, nonoperative management is often appropriate in orbital roof fractures and indicated in
 - Isolated, nondisplaced, or minimally displaced orbital roof fractures
 - Initial nonoperative course in “blow-in” fractures associated with intracerebral edema; observe for reduction of fracture fragment with resolution of cerebral edema⁶
 - Children without signs of functional deficit (eyelid position/function, extraocular muscle mobility) or significant displacement
- Higher threshold to operate in children (more likely to tolerate conservative management) but certain fracture patterns may have potential for growing skull fractures (significant displacement and dural injury⁵).
- Treatment:
 - Head of bed (HOB) elevation

- Sinus precautions: employ techniques to minimize pressure within sinuses (no nose-blowing, no sneezing with mouth closed, etc.)
- Antibiotic course not proven to be necessary, but should be considered with obvious evidence of sinus contamination of intraorbital or intracranial space
- Pain management

SURGICAL MANAGEMENT

- Initial assessment includes standard advanced trauma life support (ATLS) protocol and appropriate prioritization of treatment plan.
- Appropriate coordination of other surgical procedures
- Emergent intervention warranted with: visual/neurological compromise, retrobulbar hematoma, extraocular muscle entrapment, globe rupture, severe brain injury (ie, herniation)
- Indications for surgery:
 - Injury and functional compromise of orbital contents, including the levator complex
 - Associated dural tear with prolapse of brain tissue into the orbit
- Consider deferring procedure until edema mostly resolved, if isolated fracture and no functional compromise is present.
- Titanium or resorbable mesh fixation may be considered.

Preoperative Planning

- Comprehensive ophthalmological assessment
- Careful review of CT scan, preferably with scans displayed in the OR and easily seen from the operating position
- Careful clinical examination on table prior to surgery, to establish morbid state to provide for comparison after reduction/fixation.
- Forced duction test to establish the presence/absence of entrapment
- Place corneal protectors with thickly applied ophthalmic ointment to be able to assess correction of globe malposition and comparison to contralateral side.
- Standard perioperative IV antibiotic dose
- Infiltrate planned incisions and dissection planes with local anesthesia with epinephrine (1:1 to 400 000).
- Consider intraop radiographic imaging (CT O-arm) to evaluate reduction, especially if limited access incisions are pursued.
- Headlight helpful, especially in limited access approaches

Positioning

- The table is turned sufficiently away from the anesthesia station to provide access to each side and the head of the bed (usually 90 degrees).
- Standard HOB elevation to minimize venous pressure
- Prep and drape the entire upper face and midface (ie, both sides for intraop comparison of contours following reduction).
- Anchor drapes in hair-bearing scalp with staples.

Approach

- Four approaches are described here. The first three are “limited access” and applicable essentially to isolated orbital roof/superior orbital rim fractures largely confined to the anterior orbit or lateral frontal sinus anterior table without concomitant intracranial injury.
- Lateral brow approach (**TECH FIG 1A**):
 - For limited fractures: Gives access to orbital surface of the roof and superior orbital rim
 - Advantages: Quick, avoids unnecessary dissection, and tissue disruption
 - Disadvantages: Limited access, nerve traction injury, crush injury to orbicularis oculi muscle, and subcutaneous atrophy from retraction, postoperative brow malposition/asymmetry, risk for unfavorable scar, and inability to safely reduce roof fractures with intrusion of intracranial contents
- Supratarsal approach (**TECH FIG 1A**):
 - Similar to lateral brow approach in indication, advantages, and disadvantage, except the added risk for levator damage and brow ptosis and the improved mobility of the thinner tissue of the upper lid in translating the overlying skin/subcutis to align with the fracture
- Translaceration approach:
 - Used with associated laceration in open fractures
 - May consider extending laceration in one or more directions to provide adequate exposure
 - Advantages: Speed, minimal unnecessary disruption of the tissue
 - Disadvantages: May disrupt frontalis, sensory innervation; limited exposure and inability to safely reduce intracranial material in “blow-in” fractures
- Coronal approach (**TECH FIG 1B**):
 - The standard approach for complex or comminuted orbital roof fractures associated with intracranial injury and frontal sinus fractures

- Necessary for transcranial approach to orbital roof beyond anterior third
- Safe access for posterior orbital decompression
- Safe access to address dural injury and reduction of cranial contents
 - Advantages: Provides the widest exposure, least risk for sensory nerve damage, facilitates more accurate and faster reduction, and allows flexibility of simultaneous access to adjacent injured anatomy necessary for collaborating services, including split calvarial graft harvest if necessary
 - Disadvantages: Extensive scar, time-consuming, risk for motor nerve injury (frontal branch of CN VII), risk for temporal hollowing, discomfort, and longer recovery
- If the fracture is extensive or comminuted or involves disruption of the barrier between the brain and orbit, including dural injury, a conventional open approach via some version of a coronal incision is indicated (most cases that require operative intervention in collaboration with neurosurgical and/or ophthalmological colleagues).
- Surgical correction of the orbital roof per se may or may not require immediate attention depending on the comorbidity and the urgency therein.

TECHNIQUES

■ Lateral Brow Approach

- Place incision on the lower border of the eyebrow if the skin is completely intact to limit dissection through subcutis containing sensory nerves as they emerge from the superior orbital rim (**TECH FIG 1A**):
 - Position incision laterally to limit transection of sensory nerves.
- Distract skin/subcutis to center dissection vector on superior orbital rim.
- Continue sharply through subcutis and orbicularis muscle to the periosteum of orbital rim; if orbital septum is encountered, remain superficial to it, and redirect dissection plane superiorly toward its insertion in the orbital rim (**TECH FIG 1B**).
- Identify periosteum, and locate any traumatic laceration to serve as edge from which to dissect.
- Dissect the periosteum from underlying bone fragments to provide sufficient exposure of a periphery of intact, uninjured bones, 5 to 10 mm.

- Document, whether by photography or a quick intraoperative sketch, the configuration of fractured fragments to ensure correct reconstruction if fragment removal is necessary to achieve anatomic reduction.
- Reduce impacted fractures with fine dissector or elevator; may require removal of small, centrally located fragment to provide for optimal leverage of impacted fragments.
- If a portion of the orbital roof is displaced, removal of fragments in the superficial dissection to afford exposure necessary for adequate and stable reduction may be required.
- Reduction of multiple fragments may require stepwise approach; begin with the most distal or obscured edge, and work toward the center of dissection pocket.
- Contour plate(s) appropriately.

TECH FIG 1 • Location of skin incisions **(A)** and correct plane of dissection **(B)** in lateral brow and supratarsal approaches.

- Apply internally fixated plates and screws (titanium, primarily; resorbable plating material may be considered in these fractures as they are not prone to disruption by muscle action).
- Irrigate thoroughly.
- Perform careful layered closure of the periosteum if possible, muscle, and dermis with resorbable suture, and fine nonabsorbable suture for a precise,

tension-free superficial layer closure.

■ Supratarsal Approach

- Incision is placed in supratarsal crease, which may be difficult to find in very edematous eyelids (see **TECH FIG 1A**).
- Incise the skin and orbicularis concomitantly, encounter superficial tissue (preseptal fat or SOOF), sharply dissect through this as well, and dissect superiorly in the preseptal plane until the rim and/or fracture is encountered.
- Distract the skin/subcutis to center dissection vector on superior orbital rim.
- Continue sharply through the subcutis and orbicularis muscle to the periosteum of orbital rim; if orbital septum is encountered, remain superficial to it, and redirect dissection plane superiorly toward its insertion in the orbital rim (see **TECH FIG 1B**).
- Identify periosteum, and locate any traumatic laceration to serve as edge from which to dissect.
- Dissect periosteum from underlying bone fragments to provide sufficient exposure of a periphery of intact, uninjured bones, 5 to 10 mm.
- Document, whether by photography or a quick intraoperative sketch, the configuration of fractured fragments to ensure correct reconstruction if fragment removal is necessary to achieve anatomic reduction.
- Reduce impacted fractures with fine dissector or elevator; may require removal of small, centrally located fragment to provide for optimal leverage of impacted fragments
- If a portion of the orbital roof is displaced, removal of fragments in the superficial dissection to afford exposure necessary for adequate and stable reduction may be required.
- Reduction of multiple fragments may require stepwise approach; begin with the most distal or obscured edge, and work toward the center of dissection pocket.
- Contour plate(s) appropriately.
- Apply internally fixated plates and screws (titanium, primarily; resorbable plating material may be considered in these fractures as they are not prone to disruption by muscle action).
- Irrigate thoroughly.
- Perform careful layered closure of the periosteum if possible, muscle, and

dermis with resorbable suture, and fine nonabsorbable suture for a precise, tension-free superficial layer closure.

■ Translaceration Approach

- Remove any temporarily placed sutures.
 - Explore wound to identify frontalis, corrugator, and procerus musculature; identify supraorbital/supratrochlear nerves for gentle retraction.
 - If necessary, dissect length of sensory nerves to enable safe retraction.
 - Identify periosteum, and locate any traumatic laceration to serve as edge from which to dissect.
 - Dissect periosteum from underlying bone fragments to provide sufficient exposure of a periphery of intact, uninjured bones, 5 to 10 mm.
 - Document, whether by photography or a quick intraoperative sketch, the configuration of fractured fragments to ensure correct reconstruction if fragment removal is necessary to achieve anatomic reduction.
 - Reduce impacted fractures with fine dissector or elevator; may require removal of small, centrally located fragment to provide for optimal leverage of impacted fragments.
 - If a portion of the orbital roof is displaced, removal of fragments in the superficial dissection to afford exposure necessary for adequate and stable reduction may be required.
 - Reduction of multiple fragments may require stepwise approach; begin with the most distal or obscured edge, and work toward the center of dissection pocket.
 - Contour plate(s) appropriately.
 - Apply internally fixated plates and screws (titanium, primarily; resorbable plating material may be considered in these fractures as they are not prone to disruption by muscle action).
 - Irrigate thoroughly.
 - Perform careful layered closure of the periosteum if possible, muscle, and dermis with resorbable suture, and fine nonabsorbable suture for a precise, tension-free superficial layer closure.
-

■ Coronal Approach

- Select incision pattern (**TECH FIG 2A**):
 - Zigzag or “stealth” incisions change direction and permit hair to more effectively camouflage scar; also, provide for greater stretch of the scalp to more easily evert.
 - Straight or slightly wavy incisions are faster but ultimately more visible.
- Select incision placement:
 - Anterior hairline incision facilitates flap elevation and reduces visibility of scar but may become visible with hairline recession.
 - Placement within hair-bearing scalp likely will provide best long-term cosmetic result.
- Hair grooming with clips or rubber bands vs shaving (not with a razor blade).
- Map (with palpation) course of superficial temporal artery.
- Begin incision superior to temporal crest to avoid confusion of superficial and deep temporal fascia.
- If only a limited pericranial flap is necessary, incise the skin with scalpel through the galea in relatively short segments (5–10 cm) with immediate blunt (or sharp with scalpel) dissection in subgaleal plane anteriorly and posteriorly.
- Cauterize arteries or large galeal veins; avoid cauterization of the dermis or subcutis to minimize risk of alopecia.
- Apply Raney clips as soon as possible to stop dermal bleeding.
- Extend incision through superficial temporal fascia with care to avoid the superficial temporal vessels. In adults, well-developed periauricular musculature will be encountered that will have to be divided.
- Continue blunt dissection in the subgaleal plane anteriorly, using cautery as necessary for any transcranial emissary vessels encountered, both superiorly and laterally, leaving the deep temporal fascia and temporalis musculature undisturbed and apposed to the cranium.
- Continue in the subgaleal plane until the fracture becomes detectable, then incise the pericranium with a 5- to 10-mm margin of intact bone, and continue the dissection in the subpericranial plane over the fracture fragments, with care taken to note the position of any fragments that become dislodged during this maneuver.
- Continue subpericranial dissection as necessary past the superior orbital rim (**TECH FIG 2B**), but avoid if possible complete disruption of this plane with

respect to orbital roof fragments to maintain blood supply and optimize healing.

- If a large pericranial flap is likely to be necessary (eg, to provide lining of disrupted dura/CSF leak over the orbital roof), then dissect in the subpericranial plane between the temporal crests from the beginning, incise the pericranium at the temporal crests, and continue scalp flap dissection laterally in the subgaleal plane (again, leaving the temporalis muscle in place if temporal bone access is not necessary).
- If orbital roof is too comminuted, consider split calvarial bone graft to restore structural integrity to the orbital roof (must have vascular bed and no continuity with sinus cavity to succeed).
- Once the fracture pattern is exposed, document, whether by photography or a quick intraoperative sketch, the configuration of fractured fragments to ensure correct reconstruction if fragment removal is necessary to achieve anatomic reduction.
- Reduce impacted fractures with fine dissector or elevator; may require removal of small, centrally located fragment to provide for optimal leverage of impacted fragments.
- If a portion of the orbital roof is displaced, removal of fragments in the superficial dissection to afford exposure necessary for adequate and stable reduction may be required (**TECH FIG 2C**).
- Reduction of multiple fragments may require stepwise approach; begin with the most distal or obscured edge, and work toward the center of dissection pocket.
- Contour plate(s) appropriately.
- Apply internally fixated plates and screws (titanium, primarily; resorbable plating material may be considered in these fractures as they are not prone to disruption by muscle action; **TECH FIG 2D**).
- Irrigate thoroughly.
- If fragments of the roof are not amenable to fixation, consider titanium or other alloplastic materials to restore physical barrier between orbital tissue and anterior cranial fossa.

TECH FIG 2 • A. Different options of coronal incision placement. **B.** Surgical exposure of patient in **FIG 2**, demonstrating biplanar approach (subgaleal converted to subpericranial at level of fracture) and displacement of fracture fragments into frontal sinus, which essentially occupied the entire width of the orbital roof fracture (no intracranial extension). The *arrow* indicates the pericranial flap. **C.** Removal of fragments reveals orbital roof fracture (arrow), confined to orbital sinus cavity. **D.** Internal fixation with transversely oriented contoured low-profile titanium

plates.

- If a pericranial flap is necessary to inset intracranially at the anterior cranial base/orbital roof, then a small cranial defect of 3 to 5 mm in vertical dimension and variable width will need to be provided close to the level of the roof (see technical description of cranialization of frontal sinus).
- Anchor the pericranium with suture with or without fibrin glue.
- Closure of the scalp is over a single-closed suction-fluted drain, emerging postauricularly, and consists of interrupted resorbable suture in the pericranium over the fracture repair, then interrupted resorbable sutures every 1 to 2 cm in the galea, and then running permanent suture or staples in the skin.
- Bolster dressing is optional.

PEARLS AND PITFALLS

Coronal approach: temporal hollowing

- Avoid disinsertion of temporalis musculature or exposure of temporal fat pad.

Coronal approach injury to frontal branch of CN VII

- Begin dissection in subgaleal/subsuperficial temporal fascia plane, progress with blunt dissection in this plane in the frontotemporal region, and convert to subpericranial well superior to the course of the nerve.

Raising the pericranial flap

- Some find it easier to raise the pericranium off the already-raised scalp flap than to raise it intact off the bone following subgaleal scalp elevation because of desiccation; be sure to keep all tissues well irrigated during the prolonged exposure with the coronal approach.

Plate orientation

- One could argue in favor of orienting fixation plates to follow relaxed skin tension lines, but low-profile miniplates are difficult to palpate over the superior orbital rim and forehead.

Resorbable

- Appropriately applied when strength is not necessary, but may

plating material	cause seroma formation and bony resorption; not proven to be as effective as titanium or porous polyethylene implants for orbital roof restoration.
Change of approach	■ Even if planning for a limited approach, always be prepared (and prepare patient) for a coronal approach. ■ Have a full set of instruments available.

POSTOPERATIVE CARE

- Immediate evaluation of vision in recovery room as soon as the patient is able to be examined.
- Elevation of the head of the bed
- Sinus precautions: Employ techniques to minimize pressure within sinuses (no nose-blowing, no sneezing with mouth closed, etc.).
- Avoidance of contact activities (sports, gym, recess, etc.) for 6 weeks
- Begin scar massage after incisional edema resolved (about 2 weeks postoperatively).
- Extraocular muscle exercises as needed
- Consider a short course of prophylactic antibiotics to decrease risk for postoperative infection (devitalized bone fragments).
- Postoperative imaging is entirely dependent on the intra- and postoperative courses.

OUTCOMES

- Level 1 evidence in treatment of orbital roof fractures is lacking.
- In children, roof fractures smaller than 2 cm² are unlikely to lead to globe malposition or development of encephalocele.³
- Early intervention of orbital roof fractures with ophthalmological sequelae decreases morbidity.⁵
- That two-thirds of orbital roof fractures are associated with traumatic brain injury underscores need for multidisciplinary approach.⁷

COMPLICATIONS

- Globe displacement⁸
- Retrobulbar hematoma
- Meningitis
- Persistent CSF leak due to inadequate repair of dural tear

- Eyelid ptosis from injury to levator palpebrae superioris muscle
- Injury to orbital structures: extraocular muscles, nerves, arteries, veins, and globe
- Blindness

58 Secondary Correction of Enophthalmos

CHAPTER

David C. Matthews, Samer Abouzeid, and Edward W. Kubek

DEFINITION

- Enophthalmos refers to the posterior position of one eye relative to the contralateral eye.¹
- Secondary post-traumatic enophthalmos refers to the persistence of enophthalmos after attempted correction during the primary operation and is a common sequela to orbital trauma.
- Hypoglobus describes a vertical discrepancy in globe position.
- Secondary post-traumatic enophthalmos is the most common secondary facial deformity following primary surgery for facial trauma.²
- Until the 1970s, enophthalmos was not considered correctable.
- Tessier's work demonstrated that both acute and late enophthalmos were correctable.
- In 1982, Kawamoto first reported his technique to correct long-standing post-traumatic enophthalmos with osteotomies and bone grafting.³
- These techniques were then repeated by Manson, Wolfe, and Gruss.⁴

ANATOMY

- The bony architecture of the orbit forms two basic components, the orbital frame (comprising the rim) and the orbital pyramid with its apex pointed posteriorly (comprising the floor, roof, lateral wall, and medial orbital wall).
- The optic nerve enters the orbit at the apex of an asymmetric pyramid where the apex is oriented posteromedially and superiorly.
- General dimensions of the bony orbit are 50 mm deep, 35 mm wide, and 40 mm high.¹

- Each of the pyramid's four walls has a unique shape that contributes to globe position.¹
- Four structures of surgical importance¹:
 - The Hammer's "key area," or posterior part of the medial orbital wall (**FIG 1**).
 - S-Curvature of the posterior one-third of the orbital floor—any graft, synthetic or autologous, must sit atop the ledge created by the palatine bone posteriorly.
 - Greater wing of the sphenoid—anatomic reduction indicates proper alignment of the lateral wall and rim with the zygoma.
 - Orbital rim position—failure to anatomically reduce a displaced orbital rim (ie, the frame) prevents restoration of normal orbital shape and volume.
- Four measurements of surgical importance denote safe distances of dissection beyond key structures. Note that dissecting posteriorly to these distances will still be insufficient for secondary correction of enophthalmos, if the posterior margin of the defect is not defined.
- Dissection should be limited to:
 - Medial wall—36 mm of the anterior lacrimal crest
 - Orbital floor—35 mm of the infraorbital foramen
 - Orbital roof—30 mm of the supraorbital notch
 - Lateral wall—25 mm of the frontozygomatic suture

PATHOGENESIS (OPTIONAL)

- Post-traumatic, secondary enophthalmos occurs when the fracture pattern expands the volume of the bony orbit and is either uncorrected (**FIG 2A**) or reduced in the wrong position (**FIG 2B**):
 - As a result, the globe occupies a smaller percentage of the total space and assumes a more posterior position.
- The most common cause of secondary enophthalmos during the primary operation is inadequate posterior dissection for fear of injuring the optic nerve or globe,² followed by inadequate reduction of medial wall fractures (**FIG 3**).⁵
- Failure to re-establish the anatomic form of Hammer's key area and/or the S-curve of the posterior orbital floor can also lead to secondary enophthalmos, even in cases where the orbital floor is intact.¹

FIG 1 • Key areas of the orbit include the junction between the zygomatic bone and greater wing of the sphenoid. The palatine bone should be used as a support shelf for the bone graft.

FIG 2 • **A.** Absent reduction of the orbital floor (see *black arrow*) results in increased orbital volume leading to enophthalmos. **B.** Inadequate reduction after remote zygoma fracture demonstrates the ledge between the

zygomatic bone and the greater wing of the sphenoid.

- Late atrophy of orbital fat is rarely demonstrated and is not a cause of secondary enophthalmos⁵; furthermore, it should be the goal of the surgeon to reduce all malpositioned orbital fat noted during the workup for secondary correction.

NATURAL HISTORY

- In the early postinjury period, clinical enophthalmos is usually masked by swelling.
- As edema subsides, postsurgical patients, or those who did not seek acute care, may present with enophthalmos, in the presence or absence of diplopia.
- Globe position and healing after the primary operation or injury is considered stable at 6 months.²

PATIENT HISTORY AND PHYSICAL FINDINGS

- Normal physiologic anteroposterior variance between eyes is ≤ 2 mm.¹
- Discrepancies ≥ 3 mm can be evident to untrained observers.¹
- Normally, the globe functions as the fulcrum for the levator. Enophthalmia displaces this fulcrum causing the upper lid to appear ptotic (**FIG 4**).
- Patients may complain of eyelid thickening and impaired ability to fully open the eye.
- Preoperatively, the surgeon must document any numbness in the infraorbital and zygomaticofacial nerve distributions.

FIG 3 • Orbital floor dissection should reach the palatine bone (designated by the *arrow*).

- Hertel exophthalmometry is a noninvasive way to measure globe position. Normally, the cornea is 16 mm anterior to the lateral orbital rim. The Hertel technique is not applicable in the acute setting and inaccurate when the lateral orbital rim is displaced. In such cases, measurement relative to the ear canal may be useful.⁵

IMAGING

- A craniofacial computed tomography (CT) scan with 0.5-mm cuts should be obtained and formatted for 3D reconstructions (see **FIG 2**).
- The scan defines defects in the orbital floor, walls, and zygoma.
- CT-guided volumetric analysis can be used but is limited by an inability to predict bone resorption depending on type of bone graft (calvarial bone has less resorption than iliac bone). This analysis may be more beneficial when using preformed synthetic implants that do not resorb.⁶

SURGICAL MANAGEMENT

Preoperative Planning

- CT scan should be studied well to evaluate the dimensions of the bone that

should be harvested to reconstruct the orbital floor.

- Ophthalmologic examination should be documented preoperatively. A bedside Snellen eye chart is helpful for documenting the examination at bedside.
- Note any history of upper lid surgery for ptosis caused by enophthalmia because secondary correction of enophthalmos in this setting requires reversal of the prior upper lid operation.
- Consider a coronal incision for secondary operations to reduce large medial wall defects and old displaced zygomaticomaxillary complex fractures.
- The choice between autologous, alloplastic, metal, and bioceramic implants is guided by surgeon preference. Costlier prefabricated implants are typically reserved for secondary operations.⁷
- General principles for surgery
 - Wide subperiosteal exposure of the orbit is required to visualize the entire defect.
 - A subtarsal lower lid incision extended laterally increases exposure.

FIG 4 • When the globe is in a posterior and inferior position, the upper eyelid has no support, giving the impression of ptosis.

- Make an attempt to correct the entire defect with bone grafts.

- If necessary, the periosteum of the anterior maxilla is elevated so that orbital periosteum can be sutured to this layer to support the lower lid.
- Orbicularis ocularis is closed as well as the skin.
- In severe comminuted orbital fractures, remember that the infraorbital nerve is the key for dissection of the floor.
- Severe medial defects are approached through a coronal approach.

Patient Positioning

- The patient should be in the supine position.
- The endotracheal tube should be in the midline.
- The eyes should be closed with ophthalmic ointment.
- The face and upper shoulders will be scrubbed with Betadine and then the eyes irrigated with balanced salt solution (BSS).
- The head is draped, leaving the entire face in the surgical field.

TECHNIQUES

■ Periorbital Repair

- A transconjunctival or an infraorbital approach is made.
 - The transconjunctival approach:
 - Infiltration of local anesthetic with epinephrine
 - Incision is made posterior to the orbital septum; the incision should extend to the orbital rim.
 - The infraorbital approach:
 - Choose the highest subtarsal groove and make the skin incision.
 - Separate subcutaneous tissue until reaching the orbicularis muscle.
 - Incise the orbicularis transversely onto the orbital rim.
- A periosteal elevator dissects in the subperiosteal plane, moving from the fixed (unfractured) bone to the fracture site.
 - Periosteal elevation beyond 35 mm posteriorly endangers the optic nerve (**TECH FIG 1A**).
- After exposing the fractured area (including separation of the infraorbital nerve from the periorbital fat), the bony defect should be fully visualized.
- An autologous calvarial bone graft is taken from the parietal bone.

- After exposing the parietal skull, the graft is outlined with ink based on measurements from preoperative imaging.
- A cutting bur is used to follow the outline through the outer table.
- Bleeding from the diploe indicates proper depth.
- The graft is harvested using thin osteotomes to circumferentially free the outer table graft.
- The bone graft should be placed without fixation to span the defect.
- Ensure bony contact posteriorly, and stabilize the bone to the medial and lateral shelves of the defect.
- The graft should not extend beyond the inferior orbital rim anteriorly.
- Multiple layers of bone can be stacked until the eyes are at the same level and the “two thumbs pressure test” is similar bilaterally (**TECH FIG 1B**).
- Though bone grafts are the preferred method of treatment, synthetic implants can be used according to surgeon preference and availability of preoperative imaging with 3D modeling.
- To lessen the risk of ectropion, the malar periosteum should be resuspended.
- Before closing the skin, examine the globe’s mobility with a forced duction test.
- Two to three stitches with Vicryl 5-0 should be used to approximate orbicularis oculi edges.
- Closure is performed in one skin layer with nylon 6-0 for the infraorbital incision and Vicryl 6-0 Rapide to reapproximate conjunctivae for the transconjunctival approach.

TECH FIG 1 • A. Elevation of the periorbital soft tissue is performed from regions of normal bone toward the previous site of fracture. The elevator should not be used to dissect further than 35 mm from the orbital rim. **B.** Plates are placed on the buttresses, and any gap is covered with bone graft.

■ Zygoma Repair

- A coronal incision should be used to access the zygomatic arch.
- The temporal fascia is elevated from the zygomatic arch toward the muscle to protect the facial nerve.
- The orbital contents can also be elevated from this approach.
- The masseter muscle insertion on the zygoma is released with an elevator.
- The zygomatic arch osteotomy is made in an oblique fashion.
- The zygomaticofrontal fissure should also be cut or mobilized depending on whether the fracture site is healed or not. (Usually, the fracture is along the fissure.)
- An osteotomy is made through the old orbital rim fracture (**TECH FIG 2A**).
- A heavy bone hook—Ginestet hook—is used with a steady forward force to mobilize the zygoma, and then lateral movements are made to free it completely (**TECH FIG 2B**).

- The landmark for placing the hook is at the intersection between a vertical line passing through the lateral canthus and a horizontal line passing through the tragus.
- The zygoma is anatomically reduced.
- Anatomic alignment of the lateral orbital wall and greater wing of the sphenoid is a useful indicator of proper reduction.
- The osteotomized and reduced zygoma is fixed with titanium plates and screws (2.0 or 1.5 mm).
- Plating should be performed to the orbital rim, frontozygomatic suture, and zygomatic arch. Stable fixation at the lateral buttress must withstand the inferior pull of the masseter.

TECH FIG 2 • A. Using either a mechanical saw or a piezo saw, cuts are made along the frontozygomatic suture, the temporozygomatic suture, and lateral to the infraorbital nerve. **B.** A Ginestet hook should be used to mobilize the zygoma by pulling steadily forward, then outward, and inward.

■ Orbital Floor Repair

- Evaluation of the orbital floor bony defect should be made; a size-matched bone graft is harvested from the parietal skull.
- Multiple layers of bone can be placed to achieve symmetric positions of the

globes.

- A pseudotarsorrhaphy is performed at the end of the procedure:
 - A 5-0 Prolene horizontal mattress suture that involves the tarsus is placed between the upper and lower eyelids for temporary closure (**TECH FIG 3**).

TECH FIG 3 • The pseudotarsorrhaphy stitch should be lateral to the pupil, along the free edge of the eyelid.

PEARLS AND PITFALLS

Physical findings

- Normal physiologic anteroposterior variance between eyes is ≤ 2 mm.
- Discrepancies ≥ 3 mm can be evident to untrained observers.

Technique

- Temporalis fascia should be elevated posteriorly along the arch to protect the facial nerve.
- Oblique bone cuts should be made to allow greater bony contact and stability.
- All muscles should be freed from the zygoma for greater mobility

of the segment.

- Alignment of the lateral orbital wall and greater wing of sphenoid ensures reduction is optimal.
- Reapproximate the periosteum to avoid ectropion.
- The malar periosteum should be resuspended.
- Cautery should not be used on the orbicularis ocularis.

Postoperative care

- Eye examination should be performed when the patient is awake after surgery.
- Diplopia and eye position are assessed at 2 wk and 6 mo after surgery.

POSTOPERATIVE CARE

- An eye examination should be performed when the patient is fully awake.
- Antibiotic ointment and eye drops are applied for several days.
- Pain medications and antibiotics are given orally for 1 week.
- The patient may shower 2 days after surgery but should avoid contacting the incision line.
- A CT scan may be performed 1 week postoperatively.
- Removal of nylon stitches after 1 week.
- Eye exercises should be done immediately after edema resolution.
- Diplopia and eye position are assessed 2 weeks after the procedure and allowed 6 months to stabilize.

OUTCOMES

- Prepare patients for the possibility of subtle imperfections after secondary operations.
- Persistent diplopia from orbital trauma may not resolve with secondary correction.
- Final results will take 6 months to stabilize.
- Repeat bone grafts can be performed if the correction is insufficient.

COMPLICATIONS

- Optic nerve injury resulting in blindness
- Infraorbital nerve injury and facial numbness
- Infection or scarring of synthetic implants
- Exposure or inflammatory reaction to synthetic implants
- Nonresolution of the diplopia:

- Consider muscle injury as the cause.
- Strabismus surgery may be warranted in such cases.
- Proptosis from postoperative retrobulbar hematoma is a medical emergency requiring immediate exploration, lateral canthotomy, and immediate evacuation.
- Nonresolution of orbital dystopia.
- Ectropion (more common with subciliary approach) and upper lid malposition.
- Resorption of cranial bone graft with late recurrence of enophthalmos.^{8,9}

Section VIII: Nasal Fractures

59 Closed Nasal Fracture Correction

CHAPTER

Benjamin C. Wood

DEFINITION

- Nasal bone fracture is the most common type of facial fracture.¹
- The combination of the central positioning and anterior projection of the nose, with the delicate nature of the thin nasal bones, increases the risk of fracture from traumatic injury.

ANATOMY

- The pyramidal shape of the nose is composed of skeletal and cartilaginous structural components supporting the overlying skin and soft tissue (**FIG 1**).
- The bony structure of the nose is composed of the paired, wedge-shaped nasal bones in the midline, which articulate with the frontal process of the maxilla, the nasal process of the frontal bone, and the ethmoid and vomer.
- The cartilage structures of the nose include the paired upper lateral cartilages and lower lateral cartilages and the septum, which is composed primarily of the quadrangular cartilage.

PATHOGENESIS

- The most common cause of nasal fractures is blunt trauma, typically due to motor vehicle accidents, physical altercations, or sports-related injuries.²

FIG 1 • Nasal structural anatomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Delineate pertinent patient history, including mechanism of injury, time since injury, and any pre-existing nasal deformity or previous nasal surgery.
- Establish any prior history of nasal breathing difficulty, obstruction, or sleep apnea, including use of allergy medications, nasal sprays, or inhalers.
- External examination should focus on the severity of nasal deformity, lacerations, epistaxis, cerebrospinal fluid drainage, and pain or step-off on palpation.
- It is important to determine whether there is suspicion of a naso-orbital ethmoid (NOE) fracture on examination, which may warrant further evaluation with imaging.
- Internal examination using a nasal speculum to identify any mucosal lacerations, septal deviation, or the presence of a septal hematoma.
- Vasoconstrictive agents and topical anesthetic should be used to control bleeding and facilitate a proper internal nasal examination.
- Pediatric patients less frequently fracture the nasal bones but are more susceptible to failure to identify a septal hematoma on examination.³

IMAGING

- Nasal fractures are generally a clinical diagnosis, so radiographic imaging is of minimal utility unless there is suspicion of a more complex facial fracture pattern.

NONOPERATIVE MANAGEMENT

- Patients with minimal nasal symmetry distortion and patent nasal airways may be managed expectantly with observation and reassessment following resolution of soft tissue edema.

SURGICAL MANAGEMENT

- The timing of surgical management is dependent on the time since the injury occurred.
- Patients presenting within hours of the injury before substantial edema develops may be amenable to immediate closed nasal reduction.
- Patients presenting more than 3 or 4 hours after injury should have operative intervention deferred until sufficient time has passed to allow for resolution of edema to facilitate full visualization of the deformity.
- The decision for closed vs open nasal reduction depends on the severity of the injury.
- Simple, unilateral or bilateral, fractures are generally amenable to closed nasal reduction.
- Comminuted, closed or open, fractures may be better addressed with an open reduction.
- Septal hematomas always require immediate evaluation to avoid septal cartilage resorption and formation of a secondary nasal deformity.⁴

Preoperative Planning

- Determine whether the procedure should be performed under a local vs a general anesthetic.
- Consider patient age, compliance, medical comorbidities, and expectations.
- It is important to establish realistic patient expectations prior to surgery, as it is not uncommon to have a residual minor deformity following closed nasal reduction.
- Should an unsatisfactory deformity persist after closed nasal reduction, the patient may elect to have an open reduction and rhinoplasty in the future.

Positioning

- The patient is placed in the supine position with arms tucked.
- A shoulder roll may be placed for neck extension if necessary.

Approach

- Placement of topical and injectable anesthetic agents is performed first to allow for adequate time for the vasoconstrictive effect prior to beginning the procedure.

TECHNIQUES

■ Administration of Local Anesthetic

- Typically, both topical and injectable anesthetics are administered.
- Topical anesthetic is applied via pledgets soaked in either 4% lidocaine with oxymetazoline (Afrin) or phenylephrine hydrochloride (Neo-Synephrine) (**TECH FIG 1A**):
 - Place along nasal septum, middle turbinate, and nasal floor (**TECH FIG 1B**).
 - Leave in place for at least 7 to 10 minutes for the vasoconstrictive effect.
- Inject 1% lidocaine with epinephrine submucosally along the septum and the undersurface of the nasal bones and as a dorsal nasal and infraorbital nerve block bilaterally.
- Limit the volume of anesthetic injected so as not to obscure the deformity and results of the reduction.

TECH FIG 1 • A. Application of topical anesthetic via pledgets. **B.** Pledgets with topical anesthetic in place (7–10 minutes).

■ Reduction of Bony Nasal Pyramid and Septum

- First, measure the distance from the alar rim to the nasion of the medial canthus by placing the Goldman or Boise elevator externally along the nose (**TECH FIG 2A**):
 - This maneuver prevents advancing the elevator too far into the nasal vault in the event that there is an injury to the cribriform plate.
- Insert the elevator to the predetermined distance underlying the in-fractured nasal bone, and apply upward and outward pressure (**TECH FIG 2B**):
 - Use the combination of external digital pressure with intranasal elevator manipulation to assess adequate reduction of the nasal bone fracture.
- The nasal septum is then reduced using direct, blunt pressure to the displaced portion of the septum:
 - Alternatively, Asch or Walsham forceps may be used to straighten the nasal septum with gentle manipulation of the septum into proper alignment (**TECH FIG 2C**).

TECH FIG 2 • A. Measurement of the distance from the alar rim to the nasion. **B.** Outfracture of the nasal bone using a Boise elevator. **C.** Septal alignment using Asch forceps.

■ Nasal Airway Assessment and Splint Application

- Advance the elevator along the nasal floor to ensure that it passes to the nasopharynx without difficulty.
- Perform a nasal speculum examination to ensure patency and symmetry of the nasal airways (**TECH FIG 3A**).

- Apply a thermoplastic (Denver) external nasal splint to support and protect the reduced nasal fracture (**TECH FIG 3B**).
- Leave in place for at least 1 to 2 weeks depending on severity of fracture and patient compliance.

TECH FIG 3 • **A.** Nasal speculum examination to confirm symmetry and patency of nasal airway. **B.** Thermoplastic external nasal splint in place.

PEARLS AND PITFALLS

Physical examination

- Identify whether a septal hematoma is present, and perform hematoma evacuation immediately if needed, in order to prevent development of a late deformity.

Timing of surgery

- Defer surgical intervention until edema has fully resolved (generally 7–10 days) if the patient presents greater than 3–4 hours after injury in order to allow for optimal visualization of deformity and reduction.

Anesthetic administration

- Allow adequate time for the vasoconstrictive effect of the topical and injectable anesthetics to minimize bleeding with fracture reduction.

Nasal bone reduction	■ Measure distance from alar rim to medial canthus to prevent advancement of the elevator too far into the nasal vault.
External splint	■ Leave in place at least 1–2 weeks or longer depending on severity of fracture, patient activity level, and compliance.
Follow-up	■ Reassess patient after edema has fully resolved postreduction to determine whether there is a persistent deformity that may require open reduction and rhinoplasty.

POSTOPERATIVE CARE

- Patients should maintain the external nasal splint in place for at least 1 to 2 weeks.
- Apply ice for the first 24 hours and head elevation for the first 48 to 72 hours to facilitate faster resolution of bruising and edema.

OUTCOMES

- The goal of closed reduction is to minimize the nasal deformity in the least invasive manner possible.
- Although most patients experience significant improvement in nasal symmetry, complete correction of the nasal deformity is unlikely in the closed approach.

COMPLICATIONS

- Persistent nasal deformity due to an undiagnosed septal hematoma or unsatisfactorily corrected nasal deformity on closed reduction may result in the need for open reduction, generally within 7 to 14 days.
- Formal rhinoplasty may be performed, typically at 1 year, if necessary.

60 Open Treatment of Nasal Fractures

CHAPTER

Jeyhan Wood

DEFINITION

- Open treatment of nasal fractures involves making an incision to provide direct visualization of the fractures and achieve reduction or use of lacerations that are already present.
- The nose sits prominently on the central face and as such is the most commonly fractured facial bone, compromising up to 50% of all facial fractures¹:
 - Nasal bone fractures can occur in isolation or be associated with other facial fractures, such as those of the orbits, frontal bone, or midface.

ANATOMY

- Nasal anatomy is complex, made up of the bony vault, cartilaginous vault (paired upper lateral and lower lateral cartilages), bony septum, and cartilaginous septum (**FIG 1**):
 - The nasal bones decrease in thickness caudally; therefore, most fractures occur in the lower half of the bone.²
 - The “keystone area,” made up of the caudal aspect of the nasal bones, the cranial aspect of the upper lateral cartilages, the perpendicular plate of the ethmoid, and the cartilaginous septum, maintains support for the nasal dorsum (**FIG 1A**).

FIG 1 • AP (**A**) and lateral (**B**) view of nasal anatomy. ULC, upper laberal cartilage; LLC, lower lateral cartilage.

- The nose receives its rich blood supply from branches of both the external and internal carotid arteries. Because of this, nasal fractures are almost always associated with epistaxis, which most often stems from the Kiesselbach plexus of the anteroinferior septum.²
- Fractures can involve any of the above structures and in any combination, leading to obvious external deformity and/or functional compromise with difficulty breathing.

PATHOGENESIS

- Nasal fractures are most often the result of motor vehicle accidents, falls, altercations, and sports injuries.^{1,3}
- Nasal fractures are most often seen in males 15 to 30 years of age.
- There is no single consensus for nasal fracture classification; however, nasal fractures are often classified as lateral oblique vs frontal per the Stranc classification.^{1,3} Higuera et al. have more recently proposed a clinical classification system based on soft tissue vs bony injury, unilateral vs bilateral involvement, and simple vs comminuted fractures.²

NATURAL HISTORY

- Patients with untreated nasal fractures may experience an undesirable appearance, chronic nasal obstruction, and chronic sinusitis. This is especially

true if a septal injury is not adequately addressed.²

- With septal trauma, blood can accumulate between the mucosa and cartilage of the septum (septal hematoma), which if left undrained can eventually lead to fibrosis and resorption of the septal cartilage. This is demonstrated clinically as a saddle nose deformity.

PATIENT HISTORY AND PHYSICAL FINDINGS

■ Patient history:

- Assess the mechanism of injury (including the vector and magnitude of the force),² timing of injury, and preoperative state regarding the ability to breathe out of each nostril.
- Does the patient complain of a different appearance of the nose?
- Does the patient have a history of previous nasal trauma or nasal surgery?
- For significant maxillofacial trauma, the patient may need a complete trauma workup and appropriate precautions taken (cervical spine immobilization).
- Consider reviewing a photograph of the patient, such as a driver's license, to determine the patient's premorbid appearance.²

■ Physical examination:

- Perform an external exam looking for obvious nasal deformity (note caudal and dorsal deformity),⁴ tenderness, epistaxis, edema, periorbital ecchymoses, instability of nasal bones on palpation, step-offs, and crepitus:
 - Depending on the timing of presentation, obvious deformity may be masked by edema.
- Note any lacerations or canthal disruption, which would indicate a naso-orbital-ethmoid (NOE) fracture.
- Perform an intranasal examination with a nasal speculum and adequate light source, evaluating for septal hematoma, mucosal injury, septal deviation, airway obstruction, and clear rhinorrhea, which could be a sign of a cerebrospinal fluid (CSF) leak. Internal exam may be facilitated by using a topical decongestant.
- Assess for other facial fractures and consider nasolacrimal duct injury if the medial orbit is injured.
- Assess for uncontrollable hemorrhage. Nasal fractures may cause significant bleeding, which usually stops with manual pressure. However, persistent epistaxis may require nasal packing with Vaseline gauze or a Pope pack for anterior bleeds or intranasal placement of a Foley catheter for posterior bleeds:

- If bleeding is uncontrollable with these measures, consider interventional radiology for embolization.
- If the patient is unstable without other obvious sources of hemorrhage, consider ligation of the external carotid artery.

IMAGING

- Imaging for isolated nasal fractures is often not indicated, as treatment is based on physical exam findings.
- Plain films miss cartilaginous injury and often cannot clearly identify bony injury, with one study finding only 82% of nasal fractures successfully identified on plain film⁵:
 - Waters view (occipitomeatal) (**FIG 2A**) and lateral nasal views (**FIG 2B**) are the plain film examinations of choice, with demonstration of the orbits, maxillae, zygomatic arches, and the nasal pyramid, sidewalls, and septum.
 - If nasal bones are found to be displaced on x-ray, then those patients are at higher risk for long-term nasal deformity, and reduction is highly recommended.⁴
 - The internasal suture, nasomaxillary suture, and even the coronal suture can be mistaken for fractures on plain film.
- Computed tomography (CT) with or without 3D reconstruction has largely replaced all other modalities as far as clinical use (**FIG 2C,D**):
 - For maxillofacial CT scans, three views are ideal (axial, coronal, and sagittal) for complete evaluation of the facial skeleton.

DIFFERENTIAL DIAGNOSIS

- Nasal bone fracture/dislocation
- Cartilage injury
- Septal fracture/dislocation
- Contusion

NONOPERATIVE MANAGEMENT

- Indications:
 - Nondisplaced or minimally displaced fractures.
 - The patient desires no intervention.
- Options for conservative treatment:
 - A splint for external protection
 - Elevation of the head of the bed to decrease edema

- Ice application
- Nasal saline irrigation and/or Afrin (oxymetazoline) for nasal congestion
- Intranasal packing for epistaxis as needed

SURGICAL MANAGEMENT

- Indications include severely displaced fractures and/or dislocations of the nasal bones and/or cartilaginous vault (more than half the bridge width of the nose), fracture/dislocation of the caudal septum, open septal fracture, persistent deformity after attempted closed reduction,³ nasal fracture with substantial soft tissue injury,² or those with a delayed presentation (over 2 weeks since the injury):
 - If presenting more than 2 weeks after the initial injury, consider delaying open approach approximately 3 months to allow resolution of edema and healing of fractures.
 - Some surgeons advocate open reduction as soon as the early edema has resolved.²
- It is important for patients to have realistic expectations of outcomes. Discuss operative goals: fracture reduction and establishment of premorbid form and function vs altering the appearance of the nose with a cosmetic rhinoplasty.
- Discussion should also address the possible need for future nasal procedures.⁴

Preoperative Planning

- Review patient history and imaging studies. Define patient goals and set realistic expectations.

FIG 2 • A. Waters view of a patient with nasal trauma. No definitive fracture was identified by radiological exam; however, by clinical exam, the patient had obvious nasal deformity with deviation of the dorsum to the right. **B.** Lateral radiograph of the same patient demonstrating no definite fracture. Nonspecific irregularity of the tip of the nasal bone was noted. In a different patient, axial **(C)** and coronal **(D)** CTs demonstrate a displaced left nasal bone fracture.

- Based on the nasal injury and surrounding injuries, plan the incisions that will provide optimal exposure.
- For significantly comminuted fractures with loss of dorsal support, reconstruction beyond fracture reduction and fixation may be required (bone or cartilage grafts, suturing techniques, osteotomies for incomplete fractures).

Positioning

- The patient is positioned supine on the operating table with a shoulder roll placed for gentle extension of the neck.
- Cervical spine precautions are implemented as needed.
- Arms are tucked.
- The table is turned 90 to 180 degrees, based on surgeon preference.

Approach

- Open treatment of nasal and septal fractures can be achieved through a variety of incisions, including pre-existing adjacent lacerations, a coronal incision if other facial fractures are present (such as frontal bone) that necessitate wide exposure, an “open-sky”/glabellar approach, or an open rhinoplasty technique:
 - Advantages to the open approach include maximal surgical exposure contributing to a more accurate anatomic diagnosis, the opportunity for precise tissue handling, suturing, and grafting if needed.⁶
 - Wider exposure obtained with the open-sky approach is particularly valuable in fractures of the cribriform plate with associated CSF rhinorrhea.⁷
 - Disadvantages of the open rhinoplasty approach include the need for a transcolumellar incision, with wide dissection potentially leading to loss of support, and prolonged nasal tip edema.⁶
 - The advantage to using a coronal incision is that the surgical scar is hidden within the hairline.

TECHNIQUES

■ General Fracture Management

- For each approach, fracture management is similar.
- Expose the fractures in the subperiosteal and subperichondrial planes

(**TECH FIG 1A**). Address septal fractures/dislocations first.

- Septal fractures/dislocations may require a hemitransfixion incision for full exposure:
 - If the septum requires excision of the fractured area, leave at least a 1-cm dorsal and caudal L strut for support. Resection of the part of the vomer and perpendicular plate of the ethmoid may be necessary in severe septal fracture.³
 - The caudal septum may need to be reduced to the midline and reattached to the anterior nasal spine using 5-0 polydioxanone as a figure-of-eight suture.
- Reduce fractures using a Boies elevator intranasally and manual manipulation (**TECH FIG 1B**). If the fractured segments of nasal bone remain unstable, consider internal fixation using low-profile miniplates (0.3-mm thickness) with 1.2×4 -mm screws. For fractures with significant displacement, larger plates (0.6-mm thickness) with 1.7×4 -mm screws may be used (**TECH FIG 1C**):
 - Use the intact frontal bone or maxilla as an anchor for plating severely comminuted fractures.²
 - If using wires for internal fixation, 26- to 30-gauge wires are recommended in order to prevent palpable sharp edges.²
 - Stabilization of the fracture fragments may also be accomplished using thick absorbable sutures in figure-of-eight fashion.²
- Do not strip small bony fragments of periosteum, as this may devascularize the bony segments.

TECH FIG 1 • A. Fractures are exposed in the subperiosteal and subperichondrial planes using a periosteal elevator or freer elevator. **B.** Fractures are reduced by a combination of internal manipulation with a Boies elevator and external manual pressure. **C.** Low-profile miniplates are used for internal fixation.

■ Approaches

- For each approach, surgical preparation of the patient is similar.
- Prep the face in standard sterile fashion using Betadine. Clean inside each nostril with a Betadine-soaked cotton-tipped applicator.
- Inject local anesthetic with epinephrine around the laceration, if present, into the septum and circumferentially as a ring block around the nose.
- Insert three Afrin-soaked pledgets into each nostril.

Use of Existing Lacerations

- Open the existing laceration if it has been previously repaired (**TECH FIG 1A**).
- Irrigate the wound with saline irrigation. Debride any nonviable tissue, and remove any foreign bodies.
- Address the fractures.
- Close lacerations with monofilament absorbable suture in the deep dermis and permanent monofilament suture in the skin (**TECH FIG 1B**).
- Evaluate the nose for obvious residual deformity. Feel the dorsal nose with a wet finger for any step-offs or irregularities, and address as needed.
- Apply nasal splints.

Coronal Approach

Video p2-c060

- Place the patient's head on a Mayfield headrest.
- Temporary tarsorrhaphies are placed to maintain corneal protection throughout the procedure (**TECH FIG 2A**).

TECH FIG 2 • A. For the coronal approach, temporary tarsorrhaphy sutures are placed for corneal protection using 5-0 Prolene. **B,C.** A curvilinear incision is marked within the hairline, extending from ear to ear. The adjacent hair is clipped. **D.** The periosteum is

incised at the nasofrontal suture using Bovie needle-tip electrocautery on the cut function to allow further release of the scalp flap and improve exposure of the fractures. The supraorbital bundles are visualized and preserved. **E.** The fractures are stabilized using low-profile miniplates. The plate is anchored to the stable frontal bone. **F.** The scalp is closed with 3-0 absorbable suture in the deep dermis/galea and 4-0 absorbable suture in the skin. A Blake drain is placed through a separate stab incision in the scalp.

- Mark a curvilinear incision that extends from ear to ear. Clip the hair adjacent to the incision (**TECH FIG 2B,C**).
- Prep the scalp and face and within each nostril using Betadine. Inject local anesthetic with epinephrine around the coronal incision, into the nasal septum and circumferentially as a ring block around the nose.
- Elevate the scalp flap in the subgaleal plane anteriorly. Lateral dissection should proceed just superficial to the superficial layer of the temporalis fascia.
- The periosteum is incised approximately 2 cm superior to the supraorbital rims, and the dissection continues to the supraorbital rims and the nasal bones in the subperiosteal plane.
- If the scalp flap will not sufficiently evert, then, laterally, incise the superficial layer of temporalis fascia from the root of the temporomandibular joint along a line running at a 45-degree angle toward the supraorbital subperiosteal incision. This exposes the superficial temporal fat pad:
 - Continue the dissection using Metzenbaum scissors just deep to the superficial layer of the temporalis fascia, until the zygomatic arch is reached. Avoid dissection within the fat pad, as this may lead to unwanted temporal hollowing.
 - Incise the periosteum along the superior aspect of the zygomatic arch. This should allow sufficient eversion of the scalp flap for complete exposure of the nasal fractures (and other facial fractures that require reduction).
- Once the nasofrontal suture is exposed, longitudinal incision of the periosteum in this region may allow further release of the flap for ease of

retraction. Preserve the supraorbital bundles (**TECH FIG 2D**).

- Dissection may proceed along the dorsum to the nasal tip in the subperiosteal and subperichondrial plane, using an elevator, if desired.
- Address the fractures with fixation plates as needed (**TECH FIG 2E**).
- Close the scalp incision with 3-0 absorbable suture in the deep dermis/galeal layer and 4-0 absorbable suture for skin approximation (**TECH FIG 2F**):
 - Leave a Blake drain within the scalp wound.
 - Apply nasal splints.

“Open-Sky” or Glabellar Approach

- Mark a transverse incision within a glabellar rhytid, connecting either to a vertical incision within the nasal sidewall (open-sky) or to an upper and lower eyelid incision (horizontal Y) (**TECH FIG 3**):
 - This approach is especially useful for providing direct visualization of NOE fracture fragments needing open reduction and internal fixation.⁷
- Skin incisions are made and the fractures addressed.
- Close the glabellar incision with monofilament absorbable suture in the deep dermis and a permanent monofilament suture in the skin (**TECH FIG 4B**). Apply nasal splints.

TECH FIG 3 • A transverse incision is made within a glabellar rhytid and may either be connected to a curvilinear vertical incision within the nasal sidewall or

may bifurcate into an upper and lower eyelid incision. The vertical incision is known as the “open-sky” approach, while the upper and lower eyelid incisions are known as the “horizontal Y” or extended glabellar approach.

Open Rhinoplasty Approach

- Transcolumellar incision is marked along with marginal incisions within each nostril prior to injecting with local anesthetic (**TECH FIG 5A**).
- Skin incisions are made and the nose degloved in the subperichondrial and subperiosteal planes, as described in greater detail in “Rhinoplasty” chapters.
- If needed, expose the septum by dissection through the interdomal ligaments between the medial and middle crura of the lower lateral cartilages, using tenotomy scissors. Incise the mucosa of the caudal septum using a no. 15 blade, and then elevate the mucoperichondrium bilaterally with a Cottle elevator (**TECH FIG 5B**).
- Insert a nasal speculum for wide exposure of the septum (**TECH FIG 5C**).
- Address the fractures.
- Close transcolumellar incision with fine nylon or polypropylene suture and the marginal incisions using 5-0 absorbable suture.
- Apply nasal splints (**TECH FIG 5D,E**).

TECH FIG 4 • A. The laceration is opened if previously

repaired. **B.** The laceration is closed with absorbable suture in the deep dermis and permanent suture in the skin.

TECH FIG 5 • A. A transcolumnellar (inverted V or stairstep) incision is marked along with marginal incisions into each nostril, following the caudal border of the lower lateral cartilages. **B.** The septum is exposed through dissection of the interdomal ligaments between the lower lateral cartilages. Starting at the anterior septal angle, mucoperichondrial flaps are elevated bilaterally using a Cottle elevator. **C.** A nasal speculum is inserted to provide wide exposure of the fractured or dislocated septum. **D,E.** An Aquaplast splint and Doyle splints are applied for stabilization of the nasal dorsum and septum, respectively.

■ Dressings

- For each approach, dressing application is similar.
- Apply Mastisol and Steri-Strips to the dorsum of the nose in a triangular fashion. Trim the Aquaplast splint to overly the Steri-Strips. Soak the splint in a hot water bath until malleable. Place the Aquaplast splint on the Steri-Strips, and gently conform the splint to the contour of the nose. Add additional Steri-Strips to reinforce the splint as needed (**TECH FIG 6A**).
- Trim Doyle splints as needed, and then place within each nostril after lubricating them with Bacitracin ointment. Secure the internal splints to the caudal septum with a 3-0 chromic suture (**TECH FIG 6B**).

TECH FIG 6 • **A.** A thermoplast splint (Aquaplast) is placed for external stabilization. **B.** Internal (Doyle) splints are covered with antibiotic ointment and then secured to the caudal septum with absorbable sutures.

PEARLS AND PITFALLS

- | | |
|--------------------|--|
| Indications | ■ The surgeon should have a clear understanding of patient history, physical exam, imaging studies, and the pathology to be addressed. |
| Approach | ■ For internal fixation of open fractures, use low-profile miniplates |

(0.3-mm thickness) with 1.2 × 4-mm screws. Placement of a fixation plate where glasses rest on the nose will lead to potential plate exposure.²

Approach ■ Use the incisors as a midline reference when nasal bones are mobile and displaced.²

Approach ■ Address septal deformities first.

Technique ■ The surgeon must assess and address persistent nasal deformities (either cosmetic or functional) during the initial surgical procedure; if these are not addressed, the patient will require repeat rhinoplasty.

POSTOPERATIVE CARE

- Patients are discharged immediately after surgery with narcotic pain medication.
- Antibiotics are often prescribed while nasal packing is in place to minimize the risk of infectious complications, such as toxic shock syndrome; however, recent literature reviews indicate that routine antibiotic prophylaxis after elective nasal surgery is likely not necessary if nasal packing is to be left in place for less than 48 hours^{8,9} or for simple revision rhinoplasties.⁹
- External and internal splints are removed at 1 week. If permanent suture was used for skin closure, sutures are removed at this 1-week postoperative visit.
- Elevate the head of the bed to prevent edema.
- Apply cold compresses as tolerated for the first 24 hours to help with edema.
- No nose blowing for 4 weeks.
- Patients may use nasal saline irrigation, Afrin (oxymetazoline) or Sudafed (pseudoephedrine), as needed for congestion.

OUTCOMES

- Current management techniques for reduction of nasal fractures result in a high incidence of persistent nasal deformity, with revision rates of 14% to 50% reported in the literature.⁴
- Patients with untreated or unrecognized septal deviation or injury are likely to require a septorhinoplasty in the future, as the septum is the keystone of the correction.²
- Discrepancies remain throughout the literature regarding timing of nasal reduction, the method of reduction, and postoperative management of these patients.⁴

COMPLICATIONS

- Persistent deformity requiring repeat rhinoplasty, for both aesthetic concerns and functional problems.
- Infection: use antibiotics for intranasal packing and CSF rhinorrhea.
- Open-sky incision may heal with scar contracture, causing medial canthal webbing.
- Septal hematoma: drain urgently to prevent the late complication of saddle nose deformity, which results from fibrosis and distortion or complete necrosis of the septum.⁴
- Epistaxis: control with direct pressure and/or intranasal packing. If unusual bleeding occurs, consider coagulation studies.

Section IX: NOE Fractures

61 Naso-Orbital-Ethmoid (NOE) Fractures

CHAPTER

Craig Birgfeld and Joseph Gruss

DEFINITION

- Naso-orbital-ethmoid (NOE) fractures are fractures of the bones of the central face between the orbits involving the nose, the orbits, and the ethmoid sinuses.

ANATOMY

- The NOE region is comprised of the confluence of the nasal bones, the frontal process of the maxilla, the internal angular process of the frontal bone, the lamina papyracea of the ethmoid bone, and the lacrimal bone (**FIG 1A**).
- The NOE framework defines the nasal dorsum, the volume of the orbits, the shape of the medial orbits, and the support of the central face.
- Fractures tend to extend across the nasofrontal junction, down the medial orbital wall, across the inferior orbital rim, and across the medial buttress into the pyriform aperture (**FIG 1B**).
- NOE fractures include the complex anatomy of the medial canthal tendon attachments and nasolacrimal apparatus (**FIG 1C**).

PATHOGENESIS

- NOE fractures generally occur from blunt force trauma to the central face between the eyes, such as hitting the steering wheel or dashboard during an MVC.
- They frequently occur from self-inflicted gunshot wounds across the temple and orbits.
- NOE fractures are often components of more complex fracture patterns such

as frontal sinus fractures and panfacial fractures.

NATURAL HISTORY

- Without treatment, patients can suffer upper airway obstruction from impaction of the pyriform aperture and/or loss of nasal support resulting in a saddle nose deformity (**FIG 2**).
- Impacted and comminuted NOE fractures can change orbital volume leading to enophthalmos, dystopia, and diplopia.
- Damage to the nasolacrimal apparatus can lead to epiphora.
- Disruption of the nasofrontal outflow tract with an impacted NOE fracture can lead to frontal sinus congestion and mucocele formation.
- Untreated NOE fractures can significantly alter physical appearance.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients generally present with a history of blunt force trauma to the central upper face between the orbits.
- They may report airway obstruction, epiphora, diplopia, and alteration of physical appearance.
- Physical exam should focus first on vision, extraocular muscle involvement, and globe position.
- Patients may display telecanthus (an increased distance between the medial canthal tendons that is greater than 35 mm in adults) and hence a shortened palpebral fissure.
- The loss of dorsal nasal support leads to a saddle nose deformity with loss of nasal bridge, upturned nasal tip, and an increased nasolabial angle (normal = 90–100 degrees; **FIG 3**).
- A speculum exam should be performed to assess impaction of the lateral nasal sidewall and rule out septal fracture and/or hematoma.

IMAGING

- Fine cut (0.3–0.5 mm) maxillofacial CT scans with, at a minimum, axial and coronal views are necessary for accurate diagnosis (**FIG 4A,B**).
- Three-dimensional reconstructions are helpful to delineate anatomy and plan reduction maneuvers (**FIG 4C**).
- Sagittal views can be helpful if orbital floor fractures are also present.

DIFFERENTIAL DIAGNOSIS

- Isolated nasal bone fracture
- Isolated medial orbital wall fractures

NONOPERATIVE MANAGEMENT

- Nondisplaced NOE fractures can be managed conservatively with activity precautions and protection of the nasal dorsum with a splint.

SURGICAL MANAGEMENT

- Surgical intervention is reserved for displaced NOE fractures.
- The complexity of the intervention is determined by the amount of displacement and comminution of the segments.

FIG 1 • A. The Naso-orbital-ethmoid complex is formed by the confluence of the nasal bones, the frontal

process of the maxilla, the internal angular process of the frontal bone, the lamina papyracea of the ethmoid bone, and the lacrimal bone. **B.** Typical fracture locations of a noncomminuted bilateral NOE fracture. **C.** NOE fractures involve the complex attachments of the medial canthal tendon and the nasolacrimal apparatus.

- The goal of surgical management is to restore facial harmony by focusing on the following features:
 - Establish dorsal nasal support
 - Ensure airway patency
 - Restore normal orbital volume
 - Return the intercanthal distance to within normal range

FIG 2 • Loss of dorsal nasal support frequently occurs with NOE fractures.

Preoperative Planning

- Review of CT scans will allow planning of surgical approaches necessary to restore normal anatomy, the maneuvers necessary for reduction, and the amount and placement of rigid fixation needed for a stable framework.
- Two classification systems aid in preoperative planning:

- Manson (focus on central segment and canthal attachment):¹
 - Type 1: single segment (**FIG 5A**)
 - Type 2: comminuted (**FIG 5B**)
 - Type 3: comminuted into the canthal insertion (**FIG 5C**)

FIG 3 • Untreated NOE fractures can lead to a “saddle nose” deformity.

FIG 4 • **A,B.** Axial and coronal CT scans demonstrate a comminuted bilateral NOE fracture. **C.** NOE fractures are often associated with other upper and midface fractures such as demonstrated in this CT scan of a panfacial fracture.

- Gruss (with a focus on central face stability and associated fractures; **FIG 6**):²

- Type 1: isolated to the bony NOE region

A

B

C

FIG 5 • The Manson Classification of NOE fractures demonstrates progressive comminution of the bony segment containing the medial canthal attachment. (**A.** Type 1. Single Segment. **B.** Type 2. Comminuted. **C.** Type 3. Communitied into the canthal insertion.)

- Type 2a: bony NOE and central maxilla with loss of nasal support
 - Type 2b: bony NOE and one lateral maxilla
 - Type 2c: bony NOE and bilateral lateral maxilla
 - Type 3a: frontobasilar injury (frontal sinus involvement)
 - Type 3b: Le Fort II and Le Fort III fractures
 - Type 4a: NOE with ocular/orbital displacement
 - Type 4b: NOE with ocular/orbital displacement including orbital roof
 - Type 5: NOE fractures with loss of the bone
- The use of these classification systems also allows planning for primary bone grafting and the need for transnasal wiring and medial canthoplasty. Upon induction of anesthesia, the surgeon should place traction on the medial canthal tendon with forceps to assess its stability and determine whether wiring is required.

Positioning

- Patients are placed supine on a gel donut for a limited approach and on a Mayfield headrest for a coronal approach.
- An oral airway secured with a wire can be used for isolated NOE fractures.
- If maxillary fractures (Gruss type 3, 4, or 5) or mandibular fractures requiring intermaxillary fixation are present, a nasal airway should be avoided, and either a submental airway or tracheostomy is preferred.

Approaches

- Increasingly complex NOE fractures require greater exposure.
- Central segment (type 1) fractures impacted only at the pyriform aperture can be approached through a single gingivobuccal sulcus incision.³
- If the inferior orbital rim is also displaced; then a lower eyelid incision can be added.
- If there is also displacement at the nasofrontal junction, a Lynch incision

(semicurved incision placed in the superomedial eyelid near the glabella) can be added, or a serendipitous laceration can be utilized.

- For increasingly comminuted fractures (type 2 and above) and those requiring immediate bone grafting, a coronal incision is generally preferred.
- Though the gull-wing or open sky approach has been described, it should generally be avoided.

FIG 6 • Gruss types 1, 2, and 4 NOE fractures.

TECHNIQUES

■ Open Reduction Internal Fixation of NOE Fractures

Exposure

- Begin with exposure of all fracture sites starting with the lower eyelid approach.
- Incise sharply through the skin and orbicularis oculi muscle; then dissect bluntly in the submuscular, supraseptal plane down to the orbital rim. Incise through the arcus marginalis, and use a periosteal elevator to expose the fractured inferior orbital rim.
- Perform the coronal incision using a zigzag technique beginning within the hairline of the temple 1 cm superior and 1 cm posterior to the root of the helix. The use of microtip cautery can avoid the use of Rainey clips and subsequent alopecia. Dissect in the subgaleal plane until approximately 1 cm cephalad to the superior orbital rim; then transition to the subperiosteal plane to approach the nasofrontal junction. Carefully dissect down and around the insertion point of the medial canthal tendon attachment to join the previous lower eyelid dissection.
- Perform the gingivobuccal sulcus incision leaving a 1 cm cuff of mucosa attached to the gingiva to aid in closure. Dissect along the medial buttress to meet the lower eyelid dissection.

Fixation and Completion

- Once the fractures are exposed, place a Dingman elevator or Ash forceps into the nose, and disimpact the NOE segment to restore airway patency.
- With type 1 NOE fractures, place a miniplate along the cephalad margin of the NOE segment via the coronal incision (**TECH FIG 1A**).
 - Apply cephalad traction to the plate to reduce the fracture at the nasofrontal junction (video); then fixate the fracture.
 - The segment can then be rocked laterally with the intranasal Dingman elevator until the fractures are reduced at the orbital rim and medial buttress.
 - These are then fixated with a thin (0.5 mm) plate at the orbital rim and a thicker plate at the medial buttress (0.7–0.8 mm).
- With comminuted type 2 and type 3 NOE fractures, multiple bony fragments require reduction and fixation.
 - It is paramount to include the fragment that holds the medial canthal

attachment to restore normal intercanthal distance.

- A carefully bent 0.5-mm daisy chain plate mimicking the normal contour of the medial orbit can be used to reduce and fixate the comminuted fragments (**TECH FIG 1B**).
- If the tendon is avulsed or the bony fragment is too small to allow plate fixation, then either transnasal wiring (**TECH FIG 1C**) or a medial canthal barb can be used to re-establish normal canthal position. Overcorrection is the rule.⁴
- Next perform a nasal speculum exam to ensure patency of the airway and to assess septal integrity. If there remains inadequate dorsal nasal and tip support, then a cantilevered bone graft is placed through the coronal incision and an external rhinoplasty incision; centralize the lower lateral cartilages over top of the cantilever bone graft.
- Before closure, inspect the medial orbital wall. If there remains significant displacement of the orbital contents into the ethmoid sinuses or loss of the ethmoid contour bulge, then the medial orbital wall should be reconstructed with autograft or alloplast to prevent enophthalmos.
- After soft tissue closure, splints are applied. If the septum has been fractured, Doyle splints are placed intranasally. External compression splints are then placed along the lateral nasal sidewalls in the region of the medial canthal attachment to prevent edema and to redrape the soft tissue, recreating the normal concavity (**TECH FIG 1D**).⁵

TECH FIG 1 • **A.** In situ placement of fixation plate allows caudal traction on the displaced NOE segment and reduction of the fracture at the nasofrontal junction. **B.** A periorbital spanning plate allows fixation of the NOE fracture at the inferior orbital rim and the nasofrontal junction while maintaining medial reduction of the NOE segment, thus correcting telecanthus. **C.** Transnasal wiring technique. **D.** Placement of external splints to promote redraping of pericanthal soft tissue after narrowing of the underlying NOE segments.

PEARLS AND PITFALLS

Indications

	■ It can be helpful to compare current appearance to a preinjury photo. ■ An ophthalmology consult should be obtained to rule out concomitant injury to the globe.⁶ ■ Edema early after injury can mask the severity of enophthalmos and saddle nose deformity.
Approach	■ If a Lynch incision is used, carefully dissect around and preserve the supratrochlear neurovascular bundle.
Concomitant frontal sinus injury	■ If a concomitant frontal sinus injury requires either obliteration or cranialization, the NOE segment should be reduced and rigidly fixed first. Disimpacting the NOE fracture can reopen the frontonasal outflow tract, which needs to be obliterated.
Telecanthus	■ For type 1 NOE fractures, ensure the segment is not rotated outward before fixation. ■ For type 2 NOE fractures, be sure to capture the canthal bearing bony segment with the fixation plate. The surgeon can manually bend the plate medially to restore normal width. ■ For type 3 NOE fractures, transnasal wires or canthoplasty barb may be used to fixate the medial canthal position. ■ Overcorrection is key as the tendon tends to drift laterally.
Medial canthal webbing	■ Place external compression splints to redrape the soft tissue after fracture reduction and fixation.
Persistent enophthalmos	■ Be sure to recreate the ethmoid bulge when reconstructing the medial orbital wall fracture with either autograft or alloplast.
Nasolacrimal injury	■ Routine probing of the canalicular system is not recommended. However, if an obvious laceration involves the ducts, then they should be repaired over a Crawford tube.

POSTOPERATIVE CARE

- Tobacco avoidance and soft diet are recommended until the intraoral incisions have healed.
- Patients should avoid strenuous activity and nose blowing for 2 weeks postoperatively to prevent periorbital hematoma.
- Patients should avoid contact sports for 3 months postoperatively to ensure stable bony healing.
- The patient should be seen within 2 weeks after surgery to ensure normal

incisional healing.

- The external nasal splints and Doyle splints are removed at this clinic visit.
- It is common for patients to report transient diplopia for the first few weeks after surgery due to edema.
- It is also common for patients to exhibit epiphora after surgery due to edema that collapses the nasolacrimal apparatus.⁷
- If diplopia persists for 3 to 6 months, then referral to ophthalmology should be considered.⁸
- If epiphora persists greater than 6 months, then probing of the canalicular system and possible dacryocystorhinostomy (DCR) should be considered.

OUTCOMES

- Lack of treatment or inadequate treatment can leave permanent deformities such as telecanthus, shortened palpebral fissure, and saddle nose deformities, which are difficult, if not impossible, to correct secondarily.
- Herford et al. presented ten consecutive patients with Manson type 3 NOE fractures treated with ORIF. Of these, two patients were found to have asymmetry between the medial canthi and two had overprojection of the nasofrontal region.⁹
- Gruss et al. presented 46 consecutive patients with severe NOE fractures, 8 of whom had persistent nasolacrimal duct dysfunction and epiphora requiring DCR.⁷

COMPLICATIONS

- Complications can result from inadequate reduction of fracture segments and include:
 - Persistent telecanthus
 - Enophthalmos
 - Persistent epiphora
 - Airway obstruction
 - Saddle nose deformity
- Complications can result from surgical intervention:
 - Lower eyelid malposition
 - Scar alopecia
 - Visible scarring

Section X: Maxillary Trauma

62 Closed Reduction of Zygomatic Arch Fractures

CHAPTER

Oluwaseun A. Adetayo

DEFINITION

- The zygoma bone has four skeletal articulations—the maxilla, frontal, temporal, and sphenoid bones.
- The zygomatic arch plays a prominent role in facial skeletal profile by establishing malar projection (“cheek bones”).
- Fractures of the zygomatic arch can occur in isolation. In such cases, the tetrapod articulations are usually not violated and the remainder of the complex is stable.
- This chapter focuses on closed reduction and treatment options for isolated zygomatic arch fractures.

ANATOMY

- The zygomatic arch is a part of the zygomaticomaxillary complex (ZMC). The bone and its articulations are shown in (**FIG 1A**).
- Although the term “arch” is used to describe the bone, it is more anatomically flat in configuration for the majority of its length and is curved posteriorly.
- The zygoma is also an important landmark for the muscles of mastication.
- The zygomatic arch furnishes attachments for portions of the superficial muscular aponeurotic system (SMAS), the temporoparietal fascia (TPF), and origins for some of the muscles of facial expression and mastication.
- The highly powered masseter muscle has superficial and deep components that

take their origin from the zygomatic arch and insert into the buccal surface of the mandibular angle, ramus, and body. Portions of the deep fibers of the muscle also radiate to the anterior capsule and the articular disk of the temporomandibular joint (TMJ), thus helping to stabilize the capsule of the TMJ.

- Fractures of the zygomatic arch may disrupt the origin of the masseter and potentially affect elevation and protrusion of the mandible, resulting in pain, trismus, and occlusal problems.
- The temporalis muscle is located deep to the zygomatic arch as it inserts onto the coronoid process. Depression of an isolated arch fracture can contribute to trismus or malocclusion, via an indirect impingement on the temporalis.
- The relationship of the masseter and temporalis muscles to the zygomatic arch are depicted in **FIG 1B**.

PATIENT HISTORY AND PHYSICAL FINDINGS

- All trauma patients should undergo appropriate evaluation to rule out any concomitant facial fractures or other life-threatening injuries.
- Physical findings in patients with zygomatic arch fractures may include facial asymmetry, loss of malar projection, trismus, pain, and decreased maximum incisal opening (MIO).
- Trismus and decreased MIO can occur due to direct pull of the masseter on the arch, impingement of a displaced arch on the temporalis muscle as it inserts into the coronoid, or more directly via its compressive effect on other muscles of mastication.

FIG 1 • A. The zygoma bone and its articulations. **B.**

The relationship of the masseter and temporalis muscles to the zygomatic arch.

- Facial asymmetry may result because of actual displacement of the arch or disruption of the origin of the zygomaticus muscles, which contribute to facial expression.

IMAGING

- Various modalities including x-rays, ultrasounds, and computed tomography (CT) scans have been described for evaluation of zygoma fractures.¹⁻³
- CT scans are the most commonly utilized diagnostic tools in patients with facial fractures and provide excellent detail for the evaluation of zygomatic fractures.
- CT scan using fine cuts with axial, coronal, and 3D reconstruction are particularly helpful to evaluate the degree of displacement, impingement, malrotation, and associated fractures.

NONOPERATIVE MANAGEMENT

- Nonoperative management of isolated zygomatic arch fractures is the treatment choice in patients with the following:
 - Nondisplaced or noncomminuted arch fractures
 - Lack of trismus
 - Lack of facial or malar asymmetry
 - Normal MIO
 - Preservation of facial width and projection

SURGICAL MANAGEMENT

- Operative intervention should be considered in patients who are medically stable with sequelae of arch fractures such as trismus, malar flattening, facial asymmetry, difficulty with mouth opening, and presence of concomitant fractures.
- The goals of treatment are:
 - Anatomic restoration of three-dimensional anatomy of the zygoma with articulation and muscular complexes
 - Restoration of facial width and malar projection
 - Resolution of symptoms due to fracture
 - Restoration of orbital volume and anatomy in cases of orbitozygomatic

fractures

Preoperative Planning

- A complete history and physical examination should be performed on every patient and all concomitant injuries identified.
- Obtain imaging of choice. Most commonly used are craniomaxillofacial CT scans with fine cuts (range of 0.625- to 1.25-mm cuts at most institutions) and includes axial, sagittal, coronal, and 3D imagings as needed.
- Isolated arch fractures have been estimated to occur in 5% to 10.4% of patients with zygoma fractures, of which 59.3% are displaced or comminuted.^{2,4}

Positioning

- The patient is positioned supine on the operating table with exposure of the head and neck to facilitate access. CT scan images are displayed intraoperatively.

Approach

- The following approaches have been described for treatment of isolated zygomatic arch fractures:
 - Percutaneous approach
 - Gilles approach
 - Keen approach
 - Others

TECHNIQUES

■ Percutaneous Approach

- A 0.5- to 1-cm cutaneous incision is made directly overlying the zygoma, and a reduction instrument such as a bone hook or a Carroll-Girard T-bar screw is inserted into the body of the zygoma.⁵
- Lateral traction is placed on the isolated zygomatic arch fragment and external manual palpation is performed to guide the reduction, which is denoted by the sound of the fragment clicking back into place.
- The contralateral hand is placed at the maxilla-zygomatic arch interface on

the face and used to guide the fragment during reduction into the appropriate axial projection and skeletal relationship.

- Advantages include the minimal access incision.
- Disadvantages include presence of a facial scar and the possibility of inadequate reduction or loss of reduction.

■ Gilles Approach

- This approach was described in 1927 by Gilles, and it involves the use of a scalp incision to access the zygomatic arch fracture.
- A 2-cm incision is made in the temporal hairline 4 cm superior to the helix and extended to the superficial temporal fascia (STF), which is incised.
- This exposes the deep temporal fascia (DTF), which has two layers—the superficial layer and the deep layer—that enclose the temporalis muscle.
- Next, the superficial layer of the DTF is incised, and the surgeon gains entry into the plane between this superficial layer and the temporalis muscle.
- Dissection is performed between these layers, staying below the superficial layer of the DTF and above the temporalis muscle, thus leading to the zygomatic arch.
- The frontal branch of the facial nerve, which crosses the zygomatic arch and is enclosed within the STF, is protected.^{6,7}

TECH FIG 1 • A. Relationships of the frontal branch of the facial nerve, superficial temporal fascia, deep temporal fascia, and the zygoma. **B.** Gilles approach.

- Above the zygomatic arch at the fascial transition zone, the frontal branches of the facial nerve course on the undersurface of the STF before terminating in the frontalis and orbicularis oculi muscles. The fascial transition zone runs 1.5 to 3 cm above the superior aspect of the zygomatic arch.^{6,8} **TECH FIG 1A** illustrates the anatomic relationship in this region.
- A reduction forcep, such as a Rowe zygomatic elevator or a periosteal elevator, is placed beneath the zygoma, and lateral traction is performed to

reduce the fracture, while the contralateral hand can be used to guide reduction of the zygoma to re-establish malar projection (**TECH FIG 1B**).

- The adjunct use of fluoroscopy may be employed to guide reduction, although this practice is not routinely necessary or widespread. Fluoroscopy may aid in proper fracture reduction with closed reduction.⁹
- Reduction is usually completed by a palpable reduction into anatomic position and/or sound of the fragment clicking into position.
- Hemostasis is achieved and the incision is closed with reapproximation of all anatomic layers.
- Advantages include a camouflaged scar within the hair without facial scarring.
- Disadvantages include risk of alopecia, possibility of injury to the frontal branch of the facial nerve and the temporal fat pad, and inadequate or unstable reduction.

■ Keen Approach

- This approach was described by Keen in 1909 and utilizes an intraoral approach.
- The upper gingivobuccal sulcus of the affected side is infiltrated with local anesthetic of choice, and a 2- to 3-cm gingivobuccal sulcus incision is made running from the lateral incisor to the mesial aspect of the first molar.
- Subperiosteal dissection is performed over the maxilla to expose the zygoma and the zygomaticomaxillary buttress.
- A reduction forcep, such as a Boise or zygoma elevator, is placed deep to the zygomatic arch while palpating the malar eminence with the contralateral hand. This allows for elevation and reduction of the depressed arch with the application of a steady reduction force (**TECH FIG 2**).
- Completion of reduction is usually heralded by a palpable reduction into anatomic position and/or sound of the fragment clicking into position.
- Following reduction, the area is irrigated and the incision is closed.
- Advantages include a camouflaged scar in the oral cavity, and prevention of a temporal scar, alopecia, or facial scar.
- Disadvantages include the risk of inadequate or unstable reduction.

TECH FIG 2 • Keen approach.

■ Other

- Additional approaches for access to the fractured zygomatic arch have been described, including endoscopic approaches to assist visualization, hemicoronal incision for more direct access, fluoroscopic guidance, intraoperative ultrasonography to aid reduction, etc.^{1,3,4,7,9–12}
- The exact details of these additional techniques or adjuncts are beyond the scope of this chapter, and the reader is referred to the literature for additional information.

PEARLS AND PITFALLS

Indications

- Evaluate for concomitant fractures.

	■ Comminuted, malrotated, impinged, and unstable fractures may require open reduction and internal fixation.
Surgical technique	■ Respect the anatomic layers to avoid injury to the frontal branch of the facial nerve or atrophy of the temporal fat pad. ■ Avoid extensive stripping of the soft tissues to prevent premature midface descent secondary to soft tissue ptosis. ■ If any of the surgical techniques fail to achieve or maintain a stable reduction, then open reduction and internal fixation of the zygoma should be performed.
Failure of treatment	■ Patients whose fractures remain unstable after the various approaches described above should undergo open reduction and internal fixation of the fractures to restore normal anatomy and function.
Postoperative care	■ It is critical to identify or mark the site postoperatively. ■ A tape, sticker, or note serves as a good external reminder. ■ Monitor the patients to ensure compliance and that the reduction is stable. If any of the techniques fail, then proceed with open reduction and internal fixation with or without osteotomies.

POSTOPERATIVE CARE

- It is the author's practice to inscribe "No pressure" on a piece of wide tape, which is then gently secured to the patient's operated side over the malar eminence prior to extubation. This serves as a visual reminder to the patient, surgeon, anesthesiologist, and nursing staff caring for the patient postoperatively.
- Patient should be monitored to avoid pressure during sleep or activity on the operated side of the face while recovering from anesthesia.
- Nursing staff, treating personnel, and the patient should be educated on positioning and activity restrictions.
- Place the patient on a soft diet to avoid significant loading of the masticatory muscles during bony healing. Practices vary anywhere from 2 to 6 weeks depending on surgeon preferences, patient factors, degree of comminution, symptoms, etc.
- Maintaining good oral hygiene is key.
- There are no standardized recommendations regarding antibiotic use.

OUTCOMES

- Patients with successfully reduced zygomatic arch fractures have excellent

outcomes with the various techniques described above with minimal sequelae.

- Patients in whom reduction cannot be achieved or maintained should be considered for open reduction and internal fixation.

COMPLICATIONS

- Complications associated with each technique are described in the accompanying sections.
- General complications include:
 - Scar
 - Inability to achieve reduction
 - Inability to maintain reduction
 - Alopecia
 - Persistence of occlusal problems and facial asymmetry¹³

63 Open Correction of Zygomatic Fractures

CHAPTER

Warren Schubert and Yeshaswini Thelekkat

DEFINITION

- Zygomatic fractures are fractures of the zygomatic bone together with any one or all of its four processes—maxillary, frontal, orbital, and temporal (**FIG 1**).
- When the fracture involves only the temporal process, it is referred to as an isolated zygomatic arch fracture.
- More often, fractures involve the adjacent bones through the other processes, and the term zygomatic complex or zygomaticomaxillary complex (ZMC) fracture is more appropriate.
- ZMC fractures are also referred to as fractures of the zygoma, malar complex, quadripod, quadramalar, tetrapod, trimalar fractures, and orbitozygomatic fractures.

ANATOMY

- The zygoma maintains points of articulation with the maxilla at the zygomaticomaxillary buttress (ZMB or lateral column of the midface) and at the inferior orbital rim (IOR), the frontal bone at the zygomaticofrontal (ZF) suture, the greater wing of the sphenoid at the zygomaticosphenoid (ZS) suture, and the temporal bone at the zygomaticotemporal (ZT) suture.
- The ZS component makes up the lateral component of the orbital wall.

FIG 1 • ZMC showing fracture of four processes of the zygoma—maxillary, frontal, orbital and temporal.

- The zygoma also forms a major component of the maxillary sinus, contributing partially to the roof and to the posterolateral wall of the sinus.
- The zygoma serves as an attachment for a major portion of the masseter along the body and the zygomatic arch. The arch also serves as an attachment for both the superficial and deep portion of the deep temporal fascia along the zygomatic arch and posterolateral edge of the temporal process. The masseter muscle has a significant role in causing intrinsic deformations of the body and arch¹ (**FIG 2A**).
- The zygoma also provides attachment to the muscles of facial animation. These main muscles include the levator labii superioris along the infraorbital rim and the zygomaticus major and minor muscles along the malar eminence.¹
- The Whitnall tubercle lies on the medial aspect of the zygomatic bone, about 9 mm inferior to the ZF suture and 4 mm posterior to the lateral orbital rim (**FIG**

2B).^{2,3} This tubercle provides attachments to the lateral palpebral ligaments and the suspensory ligament of Lockwood, which forms the inferior hammock of the globe.

- This may cause a downward slant of the eyelids when there is an inferior displacement of the zygoma following trauma.^{3,4}
- A key to a successful reduction of the ZMC fracture is the alignment of the zygomaticosphenoidal suture in the lateral wall of the orbit, as this area is least likely to be comminuted.⁵
- Though it is referred to as the zygomatic “arch,” this structure is anatomically closer to being a relatively straight structure in the AP direction, rather than a curvilinear arch.
- A fracture of the ZMC is indeed complex as the zygoma helps to define the degree of midface projection and width, as well as contribute to the anatomy defining orbital volume, including the lateral orbital wall and part of the orbital floor (OF).
- Malposition of the ZMC can have a significant impact on the function of the eye as well as sensation to the infraorbital nerve.
- The various techniques that are described depend on how many points of fixation the surgeon feels are necessary for adequate reduction and fixation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The clinical presentation of the patient is dependent on the direction and strength of the force striking the midface. The patient often presents with a blunting of the malar eminence, which is commonly displaced posteriorly.

FIG 2 • A. Muscles that attach to the zygoma. **B.** Position of the Whitnall tubercle relative to the zygomaticofrontal suture with the lateral canthal ligament attached.

- Unless the fracture is a pure fracture of the zygomatic arch, all zygomatic complex fractures also result in orbital fractures, commonly of the OF and lateral orbital wall. As the orbit is involved, a complete orbital exam is required to confirm that the patient's globe and vision have not been compromised.
- The surgeon should confirm that the extraocular muscles are functioning, without evidence of entrapment of the extraocular muscles or other periorbital soft tissue.
- Diplopia may be due to entrapment or due to other malfunctions of the extraocular muscles or nerves to those muscles.
- A forced duction test may be needed to discern the difference between entrapment and malfunction of the extraocular muscles.
- Many have claimed to be able to perform a forced duction test adequately under topical anesthesia. We have generally found it necessary to have the patient completely relaxed and sedated to rule out entrapment in the acute phase of facial trauma.
- Trapdoor orbital fractures are more common in the pediatric and very young adult skeleton owing to the increased elasticity of the bone. In response to an acute periorbital impact following trauma, the floor fractures, and temporarily

bends, resulting in a linear crack. On the release of the force, the floor snaps back into its original position. There may be entrapment of the extraocular muscles and periorbita restricting the movements of the eyeball. There may be minimal signs of edema or ecchymosis externally, and CT imaging may be unremarkable when the volume of tissue entrapped is minimal. These fractures were referred to as “white-eyed blowout fracture” by Jordan et al.⁶

- The patients often present with severe pain on attempted eye movement associated with nausea and vomiting due to an unresolving oculocardiac reflex, which may be misinterpreted as being a primary intracranial injury.
- This form of entrapment requires emergent intervention, both for the comfort of the patient and to prevent prolonged muscle ischemia, which can result in a persistent diplopia.
- ZMC fractures and the associated OF fractures are commonly associated with impingement on the infraorbital nerve and numbness in that distribution of the midface.
- This should be recorded prior to any intervention to avoid postoperative concerns of an iatrogenic injury.
- A depression of the zygomatic arch medially may be associated with impingement of the coronoid process, thereby interfering with the movements of the mandible.
- This limits the patient’s ability to open or close his mouth, depending on the position of the patient’s mouth at the time of the impact and fracture of the arch and the degree of medial displacement of the arch.
- Contact of the arch with the coronoid process may also limit the excursion of the mandible from side to side (**FIG 3**).

FIG 3 • Impingement of zygomatic arch on coronoid process.

IMAGING

- The appropriate radiologic workup requires fine-cut CT.
- The ideal workup includes axial cuts, reformatted coronal cuts, and sagittal cuts through the orbit.
- For our sagittal reformatting, we prefer oblique parasagittal cuts through the orbit that follow the axial line of the optic nerve.
- In special cases of complex or comminuted fractures, a 3D reformatting may also be very useful.

NONOPERATIVE MANAGEMENT

- If the zygoma is fractured, but not displaced, surgical intervention is usually not needed.
- In isolated arch fractures, if there is no coronoid impingement or significant cosmetic deformity in the form of a depression on the cheek posterior to the malar eminence, no intervention is usually required.

SURGICAL MANAGEMENT

- Steps involved in an appropriate open reduction and internal fixation (ORIF) of a complex zygoma fracture are variable, depending on the clinical findings,

CT findings, degree of comminution, and instability of the zygoma.

- The technique first described for fixation of a ZMC fracture is that of a standard three-point fixation of the zygoma.
- The number of points of fixation needed depends on the degree of instability of the zygoma following fracture reduction.

Preoperative Planning

- An exam documenting the patient's visual acuity, movements of the globe in all directions, presence or absence of diplopia, and infraorbital nerve anesthesia/paresthesia should be included in the preoperative exam.
- Adequate preoperative axial fine cuts and coronal and oblique parasagittal reformatted CT of the midface fractures should be part of the routine preoperative workup.
- Oblique parasagittal reconstructions in the plane of the optic nerve offer the best single global view of the degree of displacement of the OF (and roof) and can present the surgeon an estimate of the length of material needed if an OF reconstruction is required.

Positioning

- Positioning should be supine.
- A decision should be made preoperatively as to whether it is necessary to perform a coronal approach, as this will affect the position of the endotracheal tube. For a pure ZMC fracture, a coronal approach is seldom needed.
- Availability of intraoperative imaging or navigation also affects patient positioning on the table and the position of the operating table relative to anesthesia providers.
- We usually prefer to have the operative table at 90 or 180 degrees from the anesthesia source.

Approach

- Fractures of the ZMC can be accessed using various transcutaneous, transconjunctival, transoral, and coronal approaches.
- The ZF suture is commonly approached transcutaneously using an upper eyelid/lateral blepharoplasty incision.
- Although a lateral brow incision is popular with surgeons in other parts of the world, the access attained is not superior to the lateral brow and results in scar alopecia in the hair of the eyebrow, which can often be quite apparent. The

lateral blepharoplasty incision is a more direct approach to the ZF fracture and leaves a scar that is barely perceptible.

- The ZF can also be accessed with a transconjunctival lateral canthotomy incision, but requires considerable traction of the soft tissues in the cephalad direction, and may result in considerable postop edema.
- The infraorbital rim (IOR) and the OF can be accessed transcutaneously using a subciliary or subtarsal (midlid) incision.
 - Alternatively, the transconjunctival incision with or without a lateral canthotomy and a transcaruncular or retrocaruncular incision (for medial orbital wall fractures and medial floor fractures) will provide excellent aesthetic exposure to the IOR and medial and lateral OF.
- The ZMB can be accessed transorally using a maxillary vestibular incision.
- The zygomatic complex and the arch can be indirectly reduced using a transoral vestibular incision (Keen approach) or an extraoral, temporal incision (Gillies approach).
- For extensive fractures, a coronal approach can be contemplated through which the lateral and medial orbital walls and supraorbital rim can be accessed in one incision. The coronal incision provides direct exposure of the zygomatic arch for reduction and plating.
 - Visualization of the arch can offer an additional landmark for achieving the proper AP projection of the malar eminence, particularly in cases where other key landmarks have been destroyed, such as when the lateral wall of the orbit is comminuted.
 - The coronal incision will have to be combined with other incisions of choice to access the IOR and ZMB.
- The specific indication for each approach is discussed in the techniques section.

TECHNIQUES

■ Three-Point Fixation of a ZMC Fracture

Approach

- In a severely displaced zygoma, the patient will require a lateral blepharoplasty incision (upper eyelid) and periorbital approach (subciliary,

midlid, or conjunctival incision).

- If there is significant displacement of the zygoma, especially with comminution of the lateral wall of the orbit, some surgeons advocate using a coronal incision to expose and plate the zygomatic arch to obtain the proper AP position of the zygomatic complex.
- It is the authors' opinion that the coronal approach often creates worse cosmetic results than the deformity it is meant to correct, including scalp scar alopecia, temporal hollowing, and the risk of injury to the frontal branch of the facial nerve.
 - We would seldom advocate including the coronal incision to address the arch unless there are additional reasons a coronal incision has to be made, such as a frontal sinus fracture or extremely comminuted landmarks of the other key reference points addressed below.
- Exposure of the ZF suture can be achieved by performing a lateral canthotomy/conjunctival incision without a blepharoplasty incision.
 - The degree of extreme pull on the soft tissues in the cephalad direction results in both a struggle of retraction intraoperatively and more postoperative periorbital edema than including an additional lateral blepharoplasty incision and heals with a minimal scar when done properly and is well concealed.
- The authors do not recommend the use of the lateral brow incision, which does not provide any better exposure to the ZF suture than a blepharoplasty incision and commonly results in an obvious permanent alopecia and what appears as a part in the hair of the eyebrow that can be noted from across the waiting room.

Not Recommended

TECH FIG 1 • A. Poor technique, with screw first placed in the frontal bone. **B.** Preferred technique, in which the first screw is placed in the zygoma so that the gap in the ZF suture can be further reduced by pulling the plate and fractured segment in the cephalad direction before placing the second screw in the frontal process.

- A ZMC fracture where there is separation of the ZF suture and comminution of the orbital rim is approached using a blepharoplasty and periorbital incision at the minimum.

First Plate

- We recommend first to plate the ZF fracture, initially with a single screw placed on each side of the fracture.
 - The ZF fracture is the poorest landmark of the various sites that will be plated to confirm the three-dimensional reduction of the zygoma.
- By using only one screw on each side of the fracture, the zygoma is still mobile and later can be swiveled into position for alignment of the orbital rim and lateral column of the midface in the area of the ZMB.
- The screw holes that are recommended to be used first should be the plate holes that are the nearest to the ZF fracture site (**TECH FIG 1**).

Reduction

- Once the initial stabilization of the ZF fracture has been done with just one screw on each side of the fracture, the zygoma is reduced.
- The authors prefer the Keen or intraoral approach. With this Keen approach, a significant force can be used to elevate the ZMC into its proper position using an appropriate zygoma elevator.
- The landmarks of the lateral orbital wall, the orbital rim, and the zygomaticomaxillary suture are used to confirm the proper alignment and reduction of the zygoma (**TECH FIG 2**).
- Some surgeons prefer the Gillies approach for elevating and repositioning the zygomatic complex.
- This approach requires an additional incision in the scalp, resulting in scar alopecia, and provides a far more indirect approach to the zygomatic arch, with several opportunities to end up in the wrong plane of dissection.

TECH FIG 2 • Intraoral (Keen) approach, with an instrument placed deep to the zygomatic arch to mobilize the ZMC.

- With a fractured zygomatic arch using a Keen approach, the surgeon can often insert a digit to actually palpate through the incision to confirm if the reduction has been achieved. This direct digital confirmation is not possible with the Gillies approach.
- Other methods of elevating the zygoma have been popularized, including using a hook under the zygomatic arch, a screw in the malar prominence to pull on, and a Carroll-Girard instrument.

Second Plate

- If three plates are required, the authors recommend plating the IOR next, after plating the ZF suture. The goal is to have the orbit and orbital rim as perfect as possible.
 - A small deformity of the lateral column of the midface is more forgivable than not having the orbit perfectly aligned (both the lateral wall and the orbital rim).
 - After plating the ZF fracture and before placing a plate on the orbital rim or the lateral column of the midface, it is key to examine the lateral wall of the orbit to confirm an adequate reduction (**TECH FIG 3A**).
- The lateral wall of the orbit commonly fractures in the area of the junction between the zygoma and the greater wing of the sphenoid. We have found that in 60% of cases, this is not comminuted, and the ZS suture is an excellent landmark for confirmation of the proper reduction of the zygoma.⁵
 - After various landmarks have confirmed the proper reduction of the zygoma, the orbital rim is plated using the surgeon's preferred periorbital approach. There are great differences in comfort and experience level using various periorbital approaches.
 - We recommend using the kind of approach with which the surgeon has the most experience (**TECH FIG 3B**).

Third Plate

- The last plate commonly used in the three-plate technique is an L-plate on the lateral column of the midface.

- The plates used at the ZF suture and the orbital rim are generally smaller (1.3 mm or smaller plates) so that the patient will not be able to palpate and complain of the plate's prominence. The L-plate is a much larger plate and offers significant stability.

TECH FIG 3 • A. Initially, the ZF plate is placed with only one screw on each side of the fracture. It is important to align the fracture along the lateral wall of the orbit, which commonly occurs at the junction of the greater wing of the sphenoid and the zygoma, prior to the placement of additional plates. **B.** Inferior orbital rim plate is placed after the ZF plate and after confirmation of the proper reduction of the ZMC, including visualization of the lateral orbital wall.

- As there is commonly significant comminution of the lateral column of the midface with these patients, we prefer a 2-mm L-plate that offers many

hole options to capture comminuted segments in variable locations (**TECH FIG 4**).

- Only after all of the other plates are placed are the final two holes of the plate at the ZF suture filled.

Other Concerns

- If reconstruction of the OF is required, this should be addressed after reduction and plating of the ZMC are complete.
- Every effort should be taken to protect the eye during the case.
 - Corneal protectors are useful.
 - A forced duction test should be performed at the end of the case to confirm that there has not been any entrapment, even in cases where a ZMC repositioning is performed without a reconstruction of the OF.
- Numbness in the infraorbital distribution is common both pre- and postoperatively. If the fracture segments appear to be impinging the nerve at the infraorbital foramen, it may be worth considering disimpacting the foramen.

TECH FIG 4 • The last plate to be placed in the three-

plate technique is the L-plate. After the placement of this plate, the final two (or more) remaining holes in the ZF plate are placed.

■ Alternative Treatments

- Various forms of intraoperative imaging are having a dramatic impact on previous traditional methods of treatment.
 - Many once thought that zygomatic arch fractures were unstable and if reduced would not hold their reduced position without plating.
 - We found that with intraoperative confirmation of a proper reduction of pure arch fractures, nine of nine consecutive fractures maintained their reduction after using the Keen approach.⁷
- In the past, it was often routine to explore the OF and reconstruct it as part of the reduction of a complex zygomatic fracture where the floor was involved or the malar eminence was telescoped posteriorly.
 - With the advent of intraoperative imaging, Wilde et al.⁸ have found that 81% of their patients did not need further surgery of the OF, the lateral wall, or the arch after a proper reduction of the zygoma, without exploration of these structures, having intraoperative visualization of an adequate reduction of the orbital walls.
 - The key is being able to visualize with radiographic imaging intraoperatively what has happened to all of the parts following the reduction of the zygoma. Once the zygoma is reduced to its proper three-dimensional projections, if the periorbita (specifically the periosteum of the orbit) has not been violated and explored, the floor will often resume its proper alignment in repositioning the ZMC due to ligamentotaxis.
- Navigation may be used intraoperatively in a similar way that intraoperative imaging is used if this technology is available to the surgeon.
 - With navigation, obtaining a preoperative CT with a fiducial guide may be necessary. With this technique, the surgeon is able to perform a virtual correction of the proper placement of the ZMC on the injured side by mirroring the proper position of the ZMC from the contralateral uninjured side.⁹
 - At the time of the surgery, the malpositioned ZMC is moved into its proper position as visualized in the virtual image.

- Rarely, a ZMC fracture will snap into reduction and be perfectly stable. There is no reason to use any plates or screws in these cases.
- If on the preoperative CT there is a fracture, but no displacement of the ZF suture, this portion of the fracture is often attached to the periosteum and hinged in a way that the surgeon may begin by only making an intraoral incision.
 - The dissection can often be carried up to the orbital rim through this intraoral incision.
 - If all of the key landmarks can be aligned and there is no (or little) comminution, a single 2-mm L-plate may be sufficient for stabilization of the ZMC fracture at the buttress.
- Every zygomatic fracture is unique. Good judgment should be used to determine how many surgical approaches are required and how many areas need to be plated. Though the authors originally supported the policy of exposing all fractures before plating, it is possible that with intraoperative imaging, fewer exposures and fewer plates and screws may be required.

TECH FIG 5 • The maximum number of plates (four-

point fixation) that might be used for a ZMC fracture. The authors would seldom find it necessary to plate the zygomatic arch, as a coronal incision would be needed. If a coronal incision is required, the plate on the arch would commonly be the second plate placed after the plate on the ZF fracture. If the arch is not plated, the orbital rim plate would commonly be the second plate placed. If there is a significant orbital floor defect, the floor would be the last part of the reconstruction after all of the other plates have been placed. Following placement of the orbital floor plate, a forced duction of the globe would be performed to confirm that the reduction of the zygoma or reconstruction of the orbital floor did not result in entrapment of the extraocular muscles or other soft tissues of the periorbital area.

- In the same way that a few fractures may attain stability without any fixation, some fractures may attain adequate stability (especially if there is no gap at the ZF fracture) with simpler one- or two-point fixation. In these noncomminuted fractures, one- or two-point fixation of the lateral wall of the midface with the possible addition of an IOR plate may be a consideration.
- In many cases in which the preoperative CT confirms a simple fracture of the IOR, this area may be adequately visualized using the intraoral approach only, without needing a periorbital incision.
- In cases of severe comminution of the multiple landmarks with significant displacement of the ZMC and a comminution of the lateral wall of the orbit, four-point fixation with exposure and fixation of the arch may be considered using a coronal incision, combined with other incisions (**TECH FIG 5**).

PEARLS AND PITFALLS

Adequate reduction and stabilization	■ Address all of the key landmarks for proper reduction, including the ZF suture, the lateral wall of the orbit, the orbital rim, and the lateral column of the midface. Make certain that the zygomatic arch is not laterally displaced, thus widening the midface, or medially displaced and impinging on the coronoid process of the mandible. Based on the degree of comminution and displacement found both on CT and intraoperatively, a decision must be made whether to use one-, two-, three-, or four-point fixation.
Intraoperative imaging	■ Availability of intraoperative imaging may help confirm an adequate reduction and possibly reduce the number of approaches that have to be used.
Navigation	■ Navigation may be used intraoperatively in the same way that intraoperative imaging is used.
Injury to the eye	■ Protect the eye by all possible means during the case. Corneal protectors are useful. A forced duction should be performed at the end of the case to confirm that there has not been entrapment of orbital soft tissue.
Injury to the infraorbital nerve	■ Numbness of the infraorbital distribution is common both pre- and postoperatively. If it appears that fracture segments are impinging on the nerve at the infraorbital foramen, it may be worth disimpacting the foramen by removal of a small amount of bone or fractured segment using an intraoral approach.

POSTOPERATIVE CARE

- Confirming that the patient's vision has not been compromised because of work in the periorbital area in the postoperative period is important.
 - Red color desaturation is also an important test as red color perception is first to be lost in optic nerve compromise.¹
- Both preoperatively and postoperatively, it is important to keep the head of the bed maximally elevated to decrease facial and, in particular, periorbital edema.
 - The use of nonsteroidal anti-inflammatory medications should be encouraged.
 - Many surgeons use steroids in the perioperative phase to help with inflammation, pain, and edema.
 - The growing dangers of excessive use of narcotics in North America need to be addressed.
 - Antibiotic use in the perioperative phase is common. Use of antibiotics is usually the surgeon's prerogative, but there is little evidence on its need and

the ideal duration of use.

- The use of ice packs may also be beneficial for pain and swelling in the immediate postoperative period.
- When conservatively treating zygomatic arch fractures by elevation alone (without plating), it is important to instruct the patient not to lie on the side of the fractured arch.
- Some surgeons advocate the use of aluminum eye shields or protectors or some other external splints to be sutured to the lateral aspect of the zygomatic arch, with the suture being driven deep to the arch. This may serve as a buttress to prevent a reduced arch fracture that has been displaced, from collapsing medially. Others argue that it also reminds the patient not to sleep on that side. Our study suggests that if the arch is properly reduced, it remains stable.⁷ Generally, if the patient is having pain, he does not lie on the fractured side of his face.

OUTCOMES

- If proper reduction is achieved and care is taken with the surgical approaches, excellent results are achieved with the anteroposterior projection and the transverse dimension of the face.

COMPLICATIONS

- Complications can include blindness, entrapment of the periorbital contents, orbital dystopia, widening of the midface, or other sequelae from an improper reduction.
- Numbness of the infraorbital nerve distribution is common but often resolves with time.
- Many surgeons have suggested a resuspension of the soft tissues after degloving the midface to prevent sagging of the tissues. Others feel an adequate layered closure of the various periorbital approaches or a more limited degloving of the soft tissue may avoid the problem of soft tissue sag.

Addressing Late Malpositioning of the Zygomaticomaxillary Complex

64

CHAPTER

Warren Schubert and Yeshaswini Thelekkat

DEFINITION

- Late malpositions of the zygomaticomaxillary complex (ZMC) result when fractures either were not addressed at the time of the original trauma or were opened and internally fixated but not properly reduced.
- The term late in this chapter refers to fractures that have healed in a malposition and require an osteotomy to mobilize and reposition the zygoma.
- The term OIF (opened and internally fixated, but not reduced) has been popularized by Joseph Gruss to suggest that rather than have a proper ORIF (open reduction and internal fixation) the patients have been opened and internally fixated but not properly reduced, resulting in a malposition of the ZMC.
- The authors have been impressed that elderly and malnourished patients with ZMC fractures—even 6 weeks after initial trauma—can occasionally be replicated and mobilized using an osteotome without a saw and then fixated using methods outlined in the chapter on primary fixation of acute ZMC fractures.
- Osteotomies in a potentially new plane should always be avoided if the exact positions of the previous fractures can be replicated.

ANATOMY

- The key is attaining proper repositioning and stabilization of the zygomatic processes and buttresses.

- Though not absolutely required, the surgeon may consider a coronal approach when addressing a late malposition. As a result, a plate on the zygomatic arch to restore the AP position of the zygoma is more likely to be considered when addressing a late malposition than in routine acute ZMC fractures.
- The goal is to re-establish the alignment and proper position of the zygomaticofrontal (ZF) fracture, the lateral wall of the orbit (junction between the greater wing of the sphenoid and the zygoma), the orbital floor, the inferior orbital rim, the lateral maxillary column of the midface, and the zygomatic arch (**FIG 1**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient may present with a variety of deformities including blunting of the malar eminence, enophthalmos, diplopia, dystopia of the eye, lateral canthal malposition, widening of the midface or depression of the zygomatic arch, and numbness in the infraorbital nerve distribution.

IMAGING

- As with an acute ZMC fracture, the appropriate radiologic workup requires fine-cut computed tomography (CT) slices.
 - The ideal workup includes axial cuts, reformatted coronal cuts, and oblique parasagittal cuts through the orbit. 3D reformatting of the midface may also be useful (**FIG 2**).
- Because the surgeon is faced with issues of remodeling of the bony fragments, exact repositioning of the osteotomized segments may present a challenge.
 - The surgeon may choose to use intraoperative CT to ensure the proper reduction of the osteotomized segments in the same way that surgeons have used this technique for acute fractures.¹
- Navigation may be used intraoperatively in a similar way that intraoperative imaging is used if this technology is available to the surgeon.²
 - With navigation, obtaining a preoperative CT with a fiducial guide may be necessary.
 - The surgeon is able to perform a virtual correction of the proper placement of the ZMC on the injured side by mirroring the proper position of the ZMC from the contralateral uninjured side.
 - At the time of surgery, the malpositioned ZMC is moved into its proper position as visualized in the virtual image.

FIG 1 • Key anatomic points that need to be realigned and fixated: (1) Fronto-zygomatic suture; (2) Zygomatic arch; (3) Infraorbital rim; (4) Zygomatico-maxillary buttress; (5) Orbital floor.

FIG 2 • **A.** AP CT of a late malposition of the ZMC in a patient who has had multiple past procedures, including a bone graft of the inferior orbital rim. It is clear that the ZMC was fixated without reduction (OIF). **B.** Lateral CT shows that a proper reduction of the ZF suture and the

zygomatic arch was never achieved.

NONOPERATIVE MANAGEMENT

- Nonoperative management is always an option.
- The authors' only experience with blindness with a ZMC repositioning occurred after an osteotomy was performed for correction of a late malposition. Our impression is that addressing a chronic deformity with enophthalmos has a significantly higher associated risk of blindness, possibly due to an orbital compartment syndrome, than does repositioning of an acute ZMC fracture.

SURGICAL MANAGEMENT

Preoperative Planning

- A complete ophthalmic examination should be performed by documenting the canthal and lid positions, identifying if there is a superior sunken sulcus of the upper eyelid, full movement of the extraocular muscles, diplopia, dystopia, and field defects.
- Exophthalmometric measurements of the degree of enophthalmos may be useful.
- As the lateral aperture of the orbit is often displaced, we prefer using a Naugle exophthalmometer over a Hertel and resting the Naugle on the frontal bar (**FIG 3A**). This assumes that the fractures being addressed do not include a displaced frontal bar.
- A McCoy facial trisquare is useful in measuring the relative location of the medial and lateral canthi to the contralateral lateral canthi (**FIG 3B**). An analysis of canthal positioning in photographs can be useful as well.
- Using either a photo or a trisquare, a horizontal line is drawn through the medial canthi to determine the relative positions of the lateral canthi.
- Our recommendation is to compare with the position of the contralateral (uninjured lateral canthi) with the eyes both open and closed.
- A complete neurologic examination including assessment of sensation of the infraorbital nerve distribution and the function of the motor branches of the facial nerve should be included in the workup.
- Preoperative photographs and high-quality CT imaging with the cuts mentioned previously, possibly with fiducials (if navigation is available), should be obtained for all patients.

FIG 3 • A. Demonstration of a Naugle exophthalmometer for measuring globe protrusion. The advantage of this exophthalmometer is that unlike the Hertel, it does not rest on the lateral orbital aperture. If the malar eminence is involved with the trauma, it is possible to slightly tip the device up so that it is resting on the frontal bar. Though the absolute measurements may be slightly distorted, the surgeon is able to gain a good idea of the relative degree of globe protrusion (or enophthalmos) compared to the uninjured side. **B.** Demonstration of the use of the McCoy facial trisquare to examine the relative position of the medial and lateral canthus.

Positioning

- Positioning of the patient should allow the surgeon access for a coronal incision.
- Because we commonly use intraoperative imaging, we position the OR table 180 degrees from the anesthesiologist, with a straight oral tube for intubation.
- If intraoperative imaging is not available, positioning the table at 90 degrees from the anesthesiologist is adequate.

Approach

- It may be a difficult decision, depending on the complexity of the case, to determine the number of surgical approaches required to perform the osteotomies and obtain an adequate reduction of the zygoma.
- A further determinant may be the exact location of the previous fractures and the required locations of the osteotomies. It may be possible to use the same surgical approaches as with the acute ZMC.
- This would include an upper blepharoplasty incision to approach the ZF suture; a periorbital dissection to expose the lateral orbital wall and floor of the orbit, as well as the inferior orbital rim; and an intraoral approach to recreate the zygomaticomaxillary fracture and to perform the osteotomy through the zygomatic arch (**FIG 4**).
- In many cases, the surgeon may determine that the safest approach (and possibly easiest) is to perform a coronal incision for access to the ZF suture, lateral orbital wall, and the zygomatic arch.

FIG 4 • Incisions: periorbital (subciliary, midlid, and orbital rim; **A**), conjunctival-lateral canthotomy (**B**), upper eyelid (blepharoplasty and brow; **C**), and intraoral (**D**). We do not recommend the orbital rim and brow

incisions due to unfavorable scars. **E.** Osteotomy of the zygomaticomaxillary segment made through the periorbital and intraoral approaches and the osteotomy of the zygomatic arch made through the intraoral incision using a Keen type of approach.

TECHNIQUES

- The first item the surgeon must address with the patient is the aspect of the deformity that bothers the patient most and the risks of various treatment options.

■ Camouflage Corrections

- The patient may choose more conservative methods of treatment or camouflage procedures to cover the deformity, without osteotomies to reposition the zygoma.
- Enophthalmos or dystopia may be adequately corrected with the use of bone grafts, cartilage, or porous polyethylene (PPE) or the use of some other filler in the orbit.
 - Posterior displacement of the malar eminence may similarly be addressed with a PPE malar implant or a bone graft.
 - In the past, methyl methacrylate and silicone implants were commonly used.
- A superior sunken sulcus of the upper eyelid can be addressed with fat grafting to camouflage the degree of the deformity.
- A malposition of the lateral canthus can be addressed by repositioning of the canthus.

■ Correction Requiring Osteotomies

- Assuming the most difficult case in which the patient prefers an osteotomy and complete correction of a healed OIF of the ZMC, at the minimum, periorbital and intraoral exposures are required.
 - Exposure of the ZF suture can theoretically be achieved by performing a

lateral canthotomy/conjunctival incision without a blepharoplasty incision. The degree of pull on the soft tissues in the cephalad direction results in both a struggle of retraction and more postoperative periorbital edema than including an additional lateral blepharoplasty incision.

- The blepharoplasty incision heals with a well-concealed scar.
- The authors condemn the use of the lateral brow incision, which does not provide any better exposure to the ZF suture than does a blepharoplasty incision and results in an obvious permanent alopecia and part within the eyebrow that can be permanently noted from across the waiting room.
- Through the periorbital incision, the globe can be retracted medially to expose the lateral wall of the orbit and superiorly to expose the orbital floor and perform the appropriate osteotomies.
 - Similarly, the orbital and intraoral exposure can be used to osteotomize the inferior orbital rim and the zygomaticomaxillary portion of the midface.
 - Using a Keen-type approach, the intraoral approach can also be used to perform the osteotomy of the zygomatic arch (see **FIG 4E**).
- Patients commonly present with an OIF and multiple problems. A coronal incision will often facilitate access for the various osteotomies and allows the surgeon to better visualize when adequate reduction is achieved.
 - In these cases, when a coronal incision is made, a blepharoplasty incision is not needed.
 - The periorbital incision and intraoral incision are still required.
 - The coronal incision also facilitates the exposure and osteotomy of the zygomatic arch (**TECH FIG 1A**).
 - In this case, the patient had significant temporal hollowing from previous procedures, and PPE has been placed to correct the temporal defect (**TECH FIG 1B**).

TECH FIG 1 • A. The coronal approach provides excellent exposure to much of the zygoma. **B.** Late malposition has been repositioned, using a coronal approach to facilitate exposure of the ZF suture, the lateral orbital wall, and the zygomatic arch (A PPE implant has been placed to correct temporal hollowing.).

■ Reconstruction and Fixation

- As with a traditional repair of an acute ZMC fracture, following the osteotomies and repositioning of the zygoma with fixation, a decision needs to be made as to whether the orbital floor or lateral orbital wall needs to also be reconstructed using titanium mesh, bone, cartilage, PPE, titanium mesh plus PPE, bioabsorbables, Silastic sheeting, and/or other less popular materials.
- The periorbita often must be mobilized to correct for enophthalmos. Controversy exists as to the extent of mobilization required to achieve adequate correction of globe protrusion.
 - In his original publication describing this procedure, Kawamoto³

recommended a complete 360-degree dissection and mobilization of the periorbita. In a later publication, Longaker and Kawamoto⁴ suggested that only the portion of the periorbita attached to the displaced ZMC needed to be mobilized. The extent of required mobilization remains controversial, and a perfect esthetic result in a patient with chronic exophthalmos remains a challenge.

- The challenges facing the surgeon include scarring of the periorbita.
- Even with a perfect reduction of the ZMC, it is possible that foreshortening of the soft tissue of the orbit and the extraocular muscles may prevent the surgeon from achieving proper globe projection.
- Although one- or two-point stabilization with plates and screws may be adequate in acute ZMC repair, because of the degree of scarring and foreshortening of the soft tissues, three- or four-point fixation is generally needed for malpositioned ZMC.
- Navigation and intraoperative imaging may also be very helpful in these cases, if the technology is available.

PEARLS AND PITFALLS

Preoperative clinical documentation

- Complete eye examination with documentation of limitations and asymmetries

Preoperative radiologic documentation

- Midface CT with reformatting and 3D reconstruction. Fiducials if navigation techniques are being considered

Camouflage alternatives

- Alternatives to osteotomies should be discussed: camouflage procedures, alternatives for correction of enophthalmos, and malar augmentation to correct asymmetry.

Mobilization of the periorbita

- The periorbita often must be mobilized to correct for enophthalmos. Controversy exists as to the extent of the mobilization that must be performed to achieve an adequate correction of globe protrusion.

Intraoperative assessment

- Use of intraoperative imaging or navigation, if available

POSTOPERATIVE CARE

- Postoperative care after addressing a late malposition of the ZMC is similar to that of acute treatment of the ZMC, with greater concern to ensure that the patient does not develop an orbital compartment syndrome.
- Performing a forced duction test at the end of the case and confirming that the patient's vision has not been compromised in the postoperative period is important.
- Keep the head of the bed maximally elevated to help decrease edema.
- The use of nonsteroidal anti-inflammatories should be encouraged. Many surgeons also use steroids in the perioperative phase to help with inflammation, pain, and swelling.
 - The growing danger of excessive use of narcotics in North America needs to be addressed.
 - Antibiotic use in the perioperative phase is common but with little evidence.
- The use of ice packs may be beneficial for pain and swelling in the immediate postoperative period.

OUTCOMES

- An improved or perfect repositioning of the zygoma is the goal. However, a perfect correction of enophthalmos and other chronic soft tissue asymmetries may be impossible to correct perfectly.

COMPLICATIONS

- Failure to adequately correct the malpositioned ZMC
- Failure to adequately correct soft tissue asymmetries
- Postoperative diplopia, dystopia, and blindness

65 Correction of Le Fort I Fracture

CHAPTER

Ananth S. Murthy

DEFINITION

- The maxilla forms most of the middle third of the facial skeleton. It is attached to the zygomatic bone and nasoethmoid area.
- There are a series of vertical and horizontal buttresses to absorb energy during impact by alternating thick and thin structures of the bones.
- Le Fort I fractures occur above the apices of the dental roots, continue across the base of the maxillary sinus, and extend to the pterygoid process.

ANATOMY

- The maxilla forms portions of the orbit, nasal cavity, and oral cavity.
- It contributes to the stability of the face by interacting with the cranium to form buttresses (**FIG 1**).
 - Nasofrontal buttress: Medially with nasal bones and glabella (frontal bone)
 - Zygomatic buttress: Laterally with the zygoma, which further articulates with the frontal bone, sphenoid, and temporal bone
 - Pterygomaxillary buttress: Posteriorly with sphenoid
- Four processes: Frontal, zygomatic, palatine, and alveolar
- During childhood, the maxilla acts as a tooth bank. As permanent teeth erupt and sinuses form, the anterior wall becomes thin and the alveolar segment becomes thick. With aging, as permanent teeth exfoliate, the alveolar segment resorbs and recedes.
- The infraorbital nerve passes through the infraorbital canal in the anterior maxilla and supplies sensation to the upper lip and lateral portion of the nose.
- Fractures of the maxilla are caused by direct impact; pattern and distribution vary depending on magnitude and direction of force.

- Le Fort I fractures usually occur in combination with other maxillary and/or facial fractures (**FIG 2**).

PATHOGENESIS

- The most common cause is a frontal impact.
- The victim is usually thrown forward, striking the midface against an object, for example, the dashboard or steering wheel of a car.
- Displacement of the maxilla is generally posterior and inferior. Pterygoid musculature aids in this direction of displacement.
- Because of this displacement, premature contact of molars often results in an anterior open bite.
- Untreated fractures will result in maxillary retrusion and decreased facial height and malocclusion.

FIG 1 • A series of vertical and horizontal buttresses

(alternating thick and thin structures of the bones) that absorb energy during impact.

FIG 2 • Le Fort I fractures occur above the level of the dental apices, across the maxillary sinus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Mobility of maxillary dentition is the hallmark of a maxillary fracture.
 - Force applied by grasping the anterior portion of the maxilla with the thumb and index finger elicits mobility of the maxilla. Integrity of the palate should be assessed in cases of segmental or split palatal fractures.
- Epistaxis, ecchymosis, and edema are seen.
 - There is midface retrusion, and malocclusion is present.
 - There may be hematoma and lacerations of the buccal mucosa.
- Evaluation for other fractures of the face, especially nasal fractures, should be performed, as isolated fractures of the maxilla are rare.

IMAGING

- Computed tomography (CT) scan is required for diagnostic examination of the maxilla. Axial cuts are best to demonstrate fractures of the maxilla.
- Three-dimensional (3D) reconstructions aid in assessing symmetry and displacement of the maxilla (**FIG 3**).

FIG 3 • CT scan showing Le Fort I maxillary fractures. Note the posterior impaction of the maxilla due to the trauma. Often segmental fractures (*arrows*) and loss of dentition (*asterisks*) are also seen.

SURGICAL MANAGEMENT

- Timing of surgery depends on the severity of injury.
 - Open, unstable fractures with hemorrhage will need emergent care.
 - Closed fractures with displacement and malocclusion should be treated within a week of injury.
- Initial treatment should be directed toward airway control, hemostasis, and maxillomandibular fixation.
- When comminuted fractures are present along with oronasal hemorrhage, and unstable midface, then, tracheostomy should be performed to obtain airway control.
- If endotracheal intubation is done, it should be converted to a nasotracheal airway so MMF can be pursued.
- The simplest and most effective way to reduce a maxillary fracture is to place the patient in occlusion with maxillomandibular fixation.

- Arch bars are useful because Le Fort fractures are usually accompanied by dentoalveolar fractures.
- Interdental wiring, dental bonding, and use of occlusal splints with quick-curing acrylic resins are also helpful in cases of displaced or missing teeth.
- The goals of treatment should be to re-establish midfacial height and projection, along with occlusion.
- Critical buttresses should be visualized, and the maxilla reduced for accurate alignment of these buttresses.
- Plate and screw fixation is necessary for control of fractures and fracture fragments.

Preoperative Planning

- Risks of tooth loss and malocclusion should be discussed with the patient. Preoperative occlusion should be determined by questioning patient or caretaker.
- Preoperative CT scans are imperative for diagnosis and planning. Intraoral exam to determine any dentoalveolar injury is important.
- If severe malocclusion is present with multiple fractures of the maxilla, then preoperative dental impressions along with model surgery and an occlusal splint may assist in obtaining maxillomandibular fixation.
- Arch bars/MMF systems, 26-G stainless steel wires, lidocaine with epinephrine, periosteal elevators, intraoral retractors, Rowe forceps, bone hooks, and 1.0 to 1.5 mm midface titanium plating systems will be needed.
- Loupe magnification with headlight assists with visualization.

Positioning

- Supine positioning with the head toward the anesthesia team allows access from both sides of the patient to the buccal sulcus and maxilla.
- Nasotracheal intubation is necessary, as MMF will be required. If fractures are unstable with oronasal hemorrhage, a tracheotomy should be considered.

Approach

- A buccal sulcus approach is the best way to visualize the maxilla.
- Preoperative injection with a local anesthetic plus epinephrine assists in hemostasis.
- A lip retractor, such as an Orringer retractor, aids with the exposure.

TECHNIQUES

■ Exposure and Reduction

- A lip retractor is placed and occlusion is assessed. A throat pack is placed.
- A buccal sulcus incision is made with a 10-mm cuff above the gingival border. When making the incision, avoid injury to the parotid duct, which is usually present at the level of the maxillary first molar.
- Using cautery, perpendicular dissection is directed toward the maxilla.
- Subperiosteal dissection is then performed with a Joseph elevator.
- The maxilla is exposed from the piriform/anterior nasal spine medially to the orbital rim superiorly (the infraorbital foramen and contents are visualized), the maxillary tuberosity laterally, and the zygoma superolaterally.
- A curved periosteal elevator can be used to dissect around the maxillary tuberosity hugging the bone until the pterygomaxillary fissure is reached by the tip of the elevator.
 - Avoid disrupting the buccal fat pad with lateral dissection; fat within the operative field becomes a nuisance during the case.
- All fractures are visualized. If vertical fracture lines are present between tooth roots, or alveolar fractures present, these are addressed first.
- Interdental wires can help align the vertical fractures.
- Rowe disimpaction forceps can be used to position the maxilla (**TECH FIG 1**).

TECH FIG 1 • A and B. The use of Rowe forceps to

reduce maxillary fractures.

■ Maxillomandibular Fixation

- Arch bars are then placed on the maxillary and mandibular dentition; 26-gauge stainless steel wires are preferred.
- MMF is achieved by placing wire loops around the arch bars.
- After MMF, attention is turned to the maxilla. The fractures along the nasomaxillary and the zygomaticomaxillary buttresses are visualized. These are aligned. If there are greater than 5 mm gaps, they should be filled with a bone graft.
- Six-hole L-shaped plates work well for fixation.
 - Monocortical drilling at 8000 RPM with copious irrigation is needed.
 - Screws of 4 to 5 mm are typically adequate for fixation.
 - Three screws on each side of the fracture are optimal.
- The horizontal portion of the L-plate is affixed just above the dental roots (or between them), and the vertical portion is used to secure it to the stable portion of the maxilla or zygoma (**TECH FIG 2**).
- After medial and lateral buttresses are secured bilaterally, MMF should be released and occlusion tested. If normal occlusion and range of motion are present, then closure can be commenced.

TECH FIG 2 • Plating schema for Le Fort I fractures. It

is important to reduce the fractures and fixate them. Plates must be bent to accommodate the curvature of the buttresses.

- After thorough antibiotic irrigation, the buccal sulcus is closed from a lateral to medial progression. Interrupted 4-0 Vicryl sutures are placed in a composite fashion so that the muscle and mucosa of the buccal sulcus are closed together in a watertight fashion.
- After removal of the throat pack, an orogastric tube is placed and suctioned, prior to extubation.

PEARLS AND PITFALLS

Dissection	■ Gentle dissection near the maxillary tuberosity prevents piercing into the buccal fat pad and the nuisance of subsequent fat herniation into the surgical field.
MMF	■ If fractures are segmental and/or severely displaced, expose the fractures, followed by open reduction and pre-emptive alignment using wire. Then, MMF can be pursued successfully followed by internal fixation. ■ Leave MMF bars/screws for a few weeks after confirmed functional occlusion.
Malocclusion	■ If malocclusion is noted (initially as lack of cuspid contact), elastics should be instituted.
Gaps	■ Gaps in the critical buttresses larger than 5 mm should be grafted with bone.

POSTOPERATIVE CARE

- If used alone, MMF should be instituted for 4 weeks. If internal fixation is performed, MMF is not required.
- A nonchew diet is instituted until the bone is healed. Typically, this means liquids for the first week, followed by blended food for 6 to 8 weeks.
- Oral hygiene is critical. Chlorhexidine mouthwash helps maintain good oral hygiene.

- Nasal cleansing with saline sprays assists in clearing clot and exudate after surgery. Nose blowing is prohibited for 3 weeks, as the increased pressure may lead to epistaxis.
- Perioperative antibiotic for 24 hours is recommended, along with postoperative pain management.
- Orthodontic referral is recommended for guided elastics if malocclusion is suspected.
- Physical therapy for jaw mobilization aids in recovery of function.

COMPLICATIONS

- Hemorrhage can be managed with ligation, packing, and MMF.
 - If hemorrhage is not controlled with these measures, interventional radiology referral for embolization may be necessary.
- Airway can be managed based on severity.
 - Intubation postoperatively may be indicated, especially if MMF is maintained.
 - Tracheostomy may be necessary if nasal intubation is not possible due to extensive trauma.
- Anesthesia of the cheek. This is usually secondary to traction and should return over the first 8 to 12 weeks.
 - If the infraorbital nerve has been severed or avulsed, permanent anesthesia will result if not repaired.
- Dehiscence of buccal sulcus incision may occur. Meticulous oral care is necessary.
 - If plates are exposed, continue oral care till bone healing is noted.
 - Hardware may be removed after healing is confirmed radiographically.
 - Instability, not exposure, causes infection and malunion.
- If multiple lacerations are noted along the gingiva, be careful to preserve a vascular cuff at the buccal sulcus incision.
 - The mucosa should be preserved centrally and not incised to preserve vascularity.
 - If compromised, gingival necrosis/retraction can be noted postoperatively.
- Postoperative infections are rare despite the continuity and involvement of oral/nasal cavities and maxillary sinuses. Infections may occur in the face of pre-existing sinusitis, or dental infection.
 - If sinusitis is suspected, traditional methods of treatment are recommended.

- If dental abscess is suspected, tooth extraction may be required.
- Malocclusion may present at several time points. If malocclusion is seen after release from MMF and with articulation of the mandible, it is necessary to remove and replace internal fixation.
- If normal occlusion is obtained intraoperatively, and malocclusion is seen within the first 4 weeks postoperatively, then MMF can be reinstituted.
- After 4 weeks, guided elastics are recommended.
- After 8 weeks, when union across the fracture is expected, reosteotomy at the Le Fort I level and fixation is necessary.

66 Correction of Le Fort II Fracture

CHAPTER

Nataliya Biskup and John van Aalst

DEFINITION

- Le Fort II is a midface fracture pattern that classically involves the critical vertical facial buttresses:
 - Nasofrontal
 - Zygomaticomaxillary
 - Pterygomaxillary (pathognomonic component of all Le Fort fractures)

ANATOMY

- The fracture starts at the zygomaticomaxillary buttress, extends through the inferior orbital rim and orbital floor to the nasofrontal buttress, and then travels posteriorly to involve the pterygomaxillary junction (**FIG 1**).
- The level of fracture across the nose is variable, ranging from as high as the nasofrontal suture to as low as the nasal cartilages.

FIG 1 • Approaches for exposure of the maxilla for reduction and plating for Le Fort II fracture.

- The attached pterygoid muscles exert a posterior and downward pull on the maxilla leading to an anterior open bite with class III occlusal relationship.
- Fractures may be bilateral or unilateral, may be combined with other Le Fort fractures, and often may be a component of a pan-facial injury.
- Medial and inferior orbital walls and nasoethmoid fractures are commonly associated fractures. If the fracture traverses the lacrimal fossa, it may involve

the lacrimal system.

PATHOGENESIS

- Le Fort II fractures result from high-velocity, blunt trauma, such as motor vehicle collisions.
- Patients will often report being thrown forward striking the midface against an object such as a steering wheel.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In addition to diffuse facial edema, malocclusion, periorbital ecchymoses, and epistaxis are often present.
- Mobility of the maxilla is a hallmark clinical finding.
- Step-offs along the inferior orbital rim may be palpable.
- The key points of examination are as follows:
 - Rule out cervical spine injury.
 - Evaluate ocular/orbital injury (vision, pupils, extraocular movement).
 - Assess cranial nerve V2 (sensation over cheek, lateral nose, and upper lip).
 - Evaluate occlusion. The expected occlusion is class III with an anterior open bite with premature posterior tooth contact.

IMAGING

- Maxillofacial CT with 3D reconstruction is the standard for diagnosis and preoperative planning. Fluid in the maxillary sinus is the most reliable indicator of maxillary fractures.

EPIDEMIOLOGY

- Most patients are males in their 30s involved in motor vehicle collisions.¹
- Among patients with maxillary fractures, the incidence of Le Fort I, Le Fort II, and Le Fort III fracture is 16% to 55%, 14% to 24%, and 13%, respectively.
 - Over half (57%) of the Le Fort fractures are combinations of the three; 89% coexist with other fractures in the maxillofacial region.²
- The incidence of associated serious eye injury is 9% and traumatic optic neuropathy 20%, and the rate becomes significantly higher for more complex fractures.^{2,3}
- Patients with Le Fort II fractures have higher injury severity scores and are more likely to need intensive care unit admission and immediate operative intervention (similar to patients with Le Fort III fractures and unlike patients

with Le Fort I injuries).^{4,5}

NONSURGICAL MANAGEMENT

- Observation is indicated in:
 - Patients with nondisplaced fractures, premorbid, unchanged occlusion, and willingness to comply with strict soft, no-chew diet
 - Edentulous patients with minimal displacement
 - Unstable patients
- Closed treatment with arch bars and guiding elastics is indicated in patients with minor malocclusion who can be reduced by closed maxillary disimpaction and manipulation.

SURGICAL MANAGEMENT

- Open treatment is indicated in patients with displaced fractures or malocclusion or those unable to comply with diet modification.

Preoperative Planning

- Rule out cervical spine injury prior to surgical correction of the facial fracture.
- Obtain ophthalmologic evaluation to rule out globe/retinal injury as intraoperative manipulation may exacerbate the injury.

Positioning

- Use nasotracheal intubation to facilitate verifying occlusion during fracture reduction.
- If nasotracheal intubation is contraindicated, place the endotracheal tube through retromolar space; if this is not possible and other lacerations are present, use submental or submandibular intubation.⁶

Approach

- Make an upper gingivobuccal sulcus incision from first premolar to first premolar, leaving a residual cuff of mucosa for final closure.
- Apply cautery directly onto maxilla the full length of the incision (**TECH FIG 1**).
- Use a Freer elevator to develop subperiosteal plane. Avoid injury to the infraorbital nerve, which exits the maxilla 1 to 2 cm below the inferior orbital rim.
- If needed, open the orbital rim via eyelid incision, either transconjunctival or

transcutaneous. If transconjunctival approach is chosen, make an incision with Bovie along the inferior fornix, well away from the tarsus. Use Bovie cautery directly onto the bone. If fracture extends medial along the rim, use a transcutaneous incision. Make an incision in the lower lid crease with a no. 15 blade. Raise a skin and orbicularis flap until arriving at the inferior orbital rim.

- Develop a subperiosteal plane to expose the infraorbital rim. Extend this approach medially via a transcaruncular approach to expose medial wall fractures if present.
- Use glabellar or coronal incisions for exposure of the nasofrontal junction, if needed.
- Close the gingivobuccal sulcus incision with 3-0 Vicryl simple interrupted. Close transcutaneous eyelid incision with 5-0 Prolene or 5-0 fast gut. Transconjunctival incisions do not need to be closed. If a lower lid incision is made, apply Frost stitch for 5 to 6 days postoperatively.

TECHNIQUES

■ Reduction

- Restore the fractured midfacial buttresses: the zygomaticomaxillary (ZM), pterygomaxillary, and nasomaxillary (NM).
- Apply Erich arch bars with 26-gauge wire.
- Expose fractures and debride callus with small curette or rongeur.
- Reduce fractures.
 - Muscular attachments to the pterygoid plates and posterior maxilla distract the maxilla posteriorly and resist reduction and fixation.
 - Use Rowe disimpaction forceps, “Stromeyer” hook, Tessier retromaxillary mobilizers, or channel retractors to passively mobilize the maxilla (**TECH FIG 1**).
 - If maxilla cannot passively be mobilized, placement of maxillomandibular fixation (MMF) can unseat the condyles such that when MMF is released, the condyles seat back into fossa, and a class III malocclusion occurs.

TECH FIG 1 • Instruments used in reduction of maxilla. From *left to right*: Rowe disimpaction forceps, Stromeyer hooks, Tessier retromaxillary mobilizer, channel retractors.

■ Fixation

- Once adequate reduction is obtained, fixate the maxilla.
- Two points of fixation are most common; however, the number of fixation points can vary from one to three depending on the degree of comminution and displacement of the fractures.
- Start plating at the most reliably reduced buttress (**TECH FIG 2A**).
- At the zygomaticomaxillary buttress, the greatest masticatory force is exerted; thus, use a larger caliber 1.5 or 2.0 mm L or straight plate.
 - Some Le Fort II fractures can be adequately reduced and plated at the ZM buttress only.
 - Place leg of plate along the most lateral portion of the ZM buttress as it has the thickest bone.
 - Place foot of plate along the alveolar bone taking care to avoid tooth roots.
 - In comminuted fractures, use longer plates in addition to smaller, shorter plates to reduce small fragments.
- At the inferior orbital rim, the forces are weaker and soft tissue is thinner; use a lower profile plate, such as a 1.2 mm, to avoid palpability.

- Rarely is plating at the nasofrontal area needed, as closed reduction of this fracture is often adequate.
 - If plating is deemed necessary, use low-profile straight, Y, or X plates.
- Use additional plates or mesh in comminuted fractures (**TECH FIG 2B**).

TECH FIG 2 • A. Most common plating configuration for noncomminuted Le Fort II fractures, includes plating of nasomaxillary/orbital rim and zygomaticomaxillary buttresses. **B.** Plating configuration used for comminuted Le Fort II fractures; shorter low-profile plates or a single sheet can be used to bridge bone defects.

■ Completion

- Following fracture fixation, release MMF and verify occlusion.
 - Passively open and close the mandible to see whether maximal intercuspation occurs and whether wear facets of the maxillary/mandibular dentition reference one another.
- Given that the maxilla is reduced by referencing its occlusion with the mandible, accurately reduce any mandible fractures and restore the posterior mandibular height and width.
 - Recognize any simultaneous palatal fractures, as this is critical to restoring accurate facial width.
- Reapply MMF depending on stability of reduction and restoration of

occlusion.

- Explore the orbital floor and medial orbital wall, if indicated, as Le Fort II fractures often involve fractures of these areas.
- Depending on degree of fracture displacement, reduction and fixation of these fractures may be indicated after plating the Le Fort II fracture.

PEARLS AND PITFALLS

Preoperative

- Evaluate ocular/orbital injury.
- Rule out cervical spine injury.

Technique

- Passive mobilization of maxilla is critical to prevent class III malocclusion.
- Rowe disimpaction forceps should be used with caution to avoid significant shear at the skull base and orbit and to prevent injury to the anterior maxillary dentition.
- Following surgery, immediately evaluate globe mobility and rule out entrapment with a forced duction test and check pupil symmetry.

POSTOPERATIVE CARE

- Vision and light perception should be monitored for 24 hours after reduction.
- Patient should elevate head of bed, apply ice, and avoid nose blowing for 4 to 6 weeks.
- Strict oral hygiene with gentle tooth brushing and non-alcohol-based mouthwash should be performed. Patients should have soft no-chew diet for 4 to 6 weeks.
- Postoperative antibiotics are recommended for 1 day after surgery. Antibiotics beyond this have not been shown to decrease infection rates.⁷
- Smoking and alcohol use should be avoided.
- Duration of MMF is variable from 2 to 6 weeks, depending on fracture stability after reduction, establishing occlusion, and amount of fracture comminution.

OUTCOMES

- Patients with more complex comminuted Le Fort fractures report more limitations due to physical and emotional problems.

- Approximately 70% of patients with Le Fort II fractures are able to return to work.
- Commonly, these patients report dissatisfaction with facial appearance and score higher on Social Avoidance and Distress scales.^{8,9}
- Other self-reported symptoms include visual problems, alteration in smell, difficulty with mastication, breathing, diplopia, and epiphora.¹⁰

COMPLICATIONS

- Early
 - Midface fractures may result in significant bleeding, which can be controlled by nasopharyngeal packing, manual fracture reduction, and/or angiographic embolization.¹¹
 - Airway obstruction may occur due to edema and posterior displacement of fracture fragments.
 - Though more rare than in mandible fractures, infection can occur, especially in patients with pre-existing sinusitis or obstruction of the maxillary sinus drainage tract.
 - Extreme care must be exercised with reduction of the maxilla as excessive force and down fracture may propagate fractures and lead to blindness. Cerebrospinal fluid leak, though rare, can also occur.
 - If the maxilla cannot be passively repositioned into appropriate reduction, consider a Le Fort I osteotomy to restore premorbid occlusion.¹²
- Late
 - The most common long-term complications include persistent infraorbital nerve paresthesias (22%); malocclusion (20%), most of which resolved with application of MMF; and orbital complications including diplopia (8%) due to extraocular muscle injury and epiphora due to nasolacrimal duct injury.¹⁰
 - Others include devitalization of teeth, nonunion, malunion, plate exposure, changes in facial appearance, and nasal airway obstruction. Delayed union is more likely to occur in comminuted fractures. Malunion often requires Le Fort I osteotomy to correct.¹⁰

67 Correction of Le Fort III Fractures

CHAPTER

Joseph Lopez and Amir H. Dorafshar

DEFINITION

- Le Fort III type fracture lines classically transverse the horizontal and vertical buttresses of the face, separating the face from the base of the skull.
- Also known as *craniofacial disjunction*, Le Fort III type fracture lines extend specifically from the lateral and medial orbital walls to the nasofrontal region and the zygomatic arches (**FIG 1**).

ANATOMY

- The facial skeleton is composed of several bones: maxilla, mandible, lacrimal, nasal, palatine, vomer, zygomatic, and inferior nasal concha bones.
- The maxilla constitutes the middle third of the face and contains the maxillary sinus.
- The maxilla and the surrounding bones compose an important system of buttresses that provide mechanical support to the face.
- These buttresses include the lateral orbital wall, zygomatic arch, nasofrontal, and lateral and medial maxillary buttresses.
- The medial and lateral maxillary buttresses are better known as the nasomaxillary buttress and zygomaticomaxillary (ZMC) buttress, respectively (**FIG 2**).
- These buttresses (ie, nasofrontal, zygomatic arch, zygomaticofrontal, lateral orbital wall) are *critical* for bony alignment and stabilization after fractures.
- The main fracture line of Le Fort III type fractures extends from the bridge of the nose through the nasofrontal process, the medial and lateral walls and floor of the orbits, the zygomaticofrontal processes, and the zygomatic arches.
- The nasal septum is also fractured, and the maxilla is separated from the

pterygoid plates.

- The maxilla is highly vascularized. The largest branch of the external carotid artery, the internal maxillary artery, supplies the midface.
- Sensation to the maxillary teeth, nasal cavity, sinuses, and facial skin overlying the maxilla is supplied by the second branch of the trigeminal nerve (infraorbital nerve).
- The infraorbital foramen is located 5 to 10 mm below the infraorbital rim in line with the medial limbus of the pupil.

PATHOGENESIS

- All maxillary fractures, including Le Fort III type, are a result of high-energy frontal or lateral impacts to the face.
- When force is exerted on the maxilla and the surrounding bones, the force is dissipated in such a way that the globe and brain are protected from injury, resulting in characteristic fracture patterns.
- Maxillary fractures are categorized using the Le Fort system.
- Le Fort I and II type fractures are less complex maxillary fractures (and are not discussed here). Le Fort III type fractures are the most complex maxillary fractures and are often the result of high-energy facial injuries.
- Le Fort III type fractures usually present in a mixed pattern with other Le Fort type fractures often present (eg, Le Fort I and II).
- Le Fort III type fractures often present with other facial fractures such as mandible, ZMC, or naso-orbital-ethmoid (NOE) fractures.
- Le Fort III type fractures are often also associated with cervical spine and skull base fractures. These fractures may be associated with airway compromise, facial bleeding, and neurological injuries.

PATIENT HISTORY AND PHYSICAL FINDINGS

- All initial trauma evaluations should consist of an assessment of airway, breathing, and circulation (ie, A, B, Cs).
- A proper primary and secondary survey should be performed in all patients with suspected facial trauma.
 - Because Le Fort III type fractures are the result of high-energy trauma, patients can often present with other life-threatening injuries such as intracranial bleeding or penetrating trauma.
- After the patient is stabilized, a complete history should be obtained (often from a family member or witnesses given that Le Fort III type fractures are

associated with neurological injuries or loss of consciousness). The following questions should be considered:

- When and where did the accident occur?
- What are the specifics of the injury (ie, object, speed, direction)?
- Was there loss of consciousness?
- Does the patient have the following symptoms:
 - Loss of vision?
 - Hearing changes?
 - Malocclusion?
 - Altered sensation?
 - Difficulty moving eyes?
 - Pain with jaw movement?
- A complete review of system should be obtained including allergies, medications, previous surgeries or medical conditions, and tetanus immunization history.
- A thorough history can be instrumental in guiding the CMF surgeon to specific injury patterns.

FIG 1 • Craniofacial disjunction/Le Fort III type fracture

in a 28-year-old healthy male after a high-impact motor vehicle collision. **A.** Le Fort III type fractures are typified by fracture lines across the bilateral lateral orbital walls and nasofrontal junctions (*red arrows*). **B.** Left zygomatic arch and zygomaticofrontal suture fracture (*blue arrows*). **C.** Right zygomaticofrontal junction fracture (*green arrow*). **D.** Stabilization achieved by reduction and fixation of the nasofrontal junction, bilateral orbital walls, and zygomaticofrontal junctions. **E,F.** Fixation of bilateral zygomaticofrontal fractures.

- Assess the head and neck region for the following:
 - Soft tissue asymmetry or skeletal deformities: Le Fort III patients often present with elongated faces or malar depression.
 - Ear canals and tympanic membrane for traumatic injuries (ie, hemotympanum, etc.) or CSF leaks
 - Nasal area for epistaxis, CSF rhinorrhea, swelling, septal deviation or hematoma, and nasal airway obstruction
 - Orbit for entrapment, ecchymosis, edema, or subconjunctival hemorrhage
 - Dentition for malocclusion, mobility of teeth, prosthetics, or mandibular/maxillary displacement during teeth contact: Le Fort III type fractures can present with malocclusion.

FIG 2 • 3D reconstructions created from CT maxillofacial coronal (**A**), axial (**B**), and sagittal (**C**) images of a 19-year-old healthy man with a Le Fort III

type fracture pattern after falling 15 ft. The *purple lines* display the nasomaxillary buttresses, and the *aqua lines* display the zygomaticomaxillary buttresses.

- Oral mucosa for swelling, lacerations, open fractures, or other pathology
- Occlusion for overjet, overbite, or open bite
- Neurovascular examination
 - Cranial nerves
 - Assess for paresthesia in the distribution of the infraorbital nerve.
- Palpation of the head and neck region for:
 - Step-offs, crepitus, clicking, or popping of the midface, nasal, frontal, and mandibular regions
 - Swelling or tenderness along buttress lines
 - Instability of the midface or maxillary mobility
 - Stability of the canthal attachments

IMAGING

- Patients suspected of having Le Fort III type or other maxillary fractures should undergo computed tomography (CT) to evaluate the fracture patterns and the need for treatment:
 - CT scans should be reviewed in the coronal, axial, and sagittal planes with particular attention to the buttresses to determine severity and types of fracture lines.
 - 3D reconstructions can often be useful for teaching purposes and for virtual surgical planning (**FIG 2**).

SURGICAL MANAGEMENT

- The two most important indications for surgical intervention of maxillary fractures are malocclusion and instability:
 - Given the complexity of Le Fort III type fractures, almost all Le Fort III type fractures present with malocclusion or instability that require surgical management.
- Other relative indications for Le Fort III type surgical management include uncontrolled bleeding and airway stabilization:
 - Because Le Fort III type fractures are associated with extensive soft tissue injury and swelling, nasal and oral airflow can be compromised.

- The main goal of operative management is to re-establish proper occlusion.
- Timing of surgical management is dictated largely by concomitant injuries.

Preoperative Planning

- CT scan should be reviewed to determine the correct combination of approaches.

Positioning

- The patient is positioned supine on the operating table with a shoulder roll to facilitate neck extension.
- Neck extension is contraindicated if the patient is suspected to have or has a spine injury.
 - In these situations, we prefer to defer surgical correction until the neck has been clinically or radiologically cleared. In extenuating circumstances when the neck cannot be cleared, or if there is indeed a cervical neck fracture, we will ask permission from the spine team to proceed with caution by either using an adapted silicone headrest or two 3-L intravenous solution bags taped on either side of the patient's head, to keep the neck in a neutral position throughout the duration of the surgery.

Approach

- Because of the complexity of Le Fort III type fractures, exposure often is achieved with multiple approaches including coronal flaps, lower eyelid incisions, and upper buccal incisions.

TECHNIQUES

■ Repair With Coronal Flap, Miniplate Fixation, and Intermaxillary Fixation

Airway Establishment and Exposure

- After a thorough discussion with the trauma and anesthesia team, the best method for airway management is determined.
 - Nasal intubation can be accomplished with a standard endotracheal tube or a nasal RAE tube which is longer and can be more easily secured.

- Careful attention to skull base fractures is mandatory when using nasal intubation.
- If postoperative airway compromise is of great concern, a tracheostomy must be considered.
- The face is prepped and draped in sterile fashion.
- Intermaxillary arch bars or screws should be applied at the outset of the case to assist with achievement of satisfactory occlusion with anatomical fracture reduction.
- A coronal incision is made from the preauricular crease above the pinnae across the temples to form a gentle curve behind the hairline.
- 1% lidocaine with 1:100 000 epinephrine can be injected to the incision line to control bleeding.
- Raney scalp clips can be applied at the incision for hemostasis. These clips can cause severe alopecia if left in place for a prolonged period of time, however. The authors prefer not to apply Raney clips and prefer to obtain hemostasis of the scalp during the incision.
- Hair can be held out of the way with elastic bands covered with towels attached to the scalp.
- Branches of the superficial temporal artery are clamped and ligated with suture.
- A subperiosteal plane is developed, and the scalp and forehead are elevated over the supraorbital rim (**TECH FIG 1**).
- Laterally, the dissection should be developed in the plane just superficial to the temporalis muscle fascia.
- The dissection is continued once one reaches the supraorbital rim with careful attention to preserve the supraorbital and supratrochlear vessels.
- While the flap is elevated, the periosteum is incised along the zygomaticofrontal buttress.
- If the zygomatic arch needs to be exposed, the supratrochlear and supraorbital vessels and nerves can be released by making osteotomies at the supraorbital foramina.
- The nasal bridge fracture can be exposed by elevating the periosteum from the frontal process of the maxilla and nasal bones. At times, the periosteum needs to be incised to better expose the nasal bones.
- To expose the infraorbital rim and lower maxilla, an upper gingival buccal incision can be made.

Fracture Reduction and Fixation

- Once all fractures are exposed, the Le Fort III fracture can be reduced with Rowe disimpaction forceps as needed. However, osteotomies may be needed to fully mobilize the fractured segment if the midface is impacted and cannot be disimpacted using the Rowe disimpaction forceps (**TECH FIG 2A**).

TECH FIG 1 • A coronal incision is made and a subgaleal (or subperiosteal) plane is developed. The scalp and forehead are elevated over the supraorbital rim. Near the supraorbital rim, a subperiosteal plane is developed (or continued) with careful attention to preserve the supraorbital and supratrochlear vessels. Laterally, the dissection should be developed in the plane just superficial to the temporalis muscle fascia.

While the flap is elevated, the periosteum is incised along the zygomaticofrontal buttress down to the zygomatic arch.

TECH FIG 2 • A. Once all fractures are exposed, the Le Fort fracture can be reduced with Rowe disimpaction forceps as needed. However, osteotomies may be needed to fully mobilize the fractured segment if the midface is impacted and cannot be disimpacted using the Rowe disimpaction forceps. **B.** Once pretraumatic occlusion is achieved with intermaxillary fixation and all the buttress fractures are aligned, plating can proceed.

- Once pretraumatic occlusion is achieved with intermaxillary fixation (IMF) and all the buttress fractures are aligned, plating can proceed (**TECH FIG 2B**).
- Large bone gaps (5–10 mm) should be treated with bone grafts.
- The most important suture to fixate the lateral orbital walls is at the zygomaticofrontal junction. A miniplate with at least two holes on each side of the fracture must be placed with the bone in an adequately reduced position (**TECH FIG 3**).

- If the nasofrontal process is unstable, fine 0.5-mm plates, small interosseous wires, or 2-0 PDS sutures can be placed to approximate all the fragments.
 - If the orbital rim needs repair, an eyelid exposure can assist in fixating the reduced orbital segments. The authors' preferred eyelid approach is the transconjunctival incision.
 - The coronal flap, upper gingivobuccal, and eyelid incisions are closed in layers.
 - The patient is placed on perioperative antibiotics for 24 hours and imaging obtained as needed.
-

TECH FIG 3 • Le Fort III type fracture in a 25-year-old man who presented after an assault. **A–C.** Preoperative imaging revealed Le Fort III and I type fractures. **D–F.** Once pretraumatic occlusion was achieved with intermaxillary fixation, all the buttress fractures were aligned, and fixation via plating was performed.

PEARLS AND PITFALLS

Indications	■ Surgical indications for Le Fort III type fractures are instability and malocclusion.
Goals	■ Restore normal occlusion. ■ Restoration of facial height, width, and projection.
Approach	■ Given the complexity of Le Fort III type fractures, multiple approaches are necessary to reduce all fractures lines: these include the coronal flap, upper gingivobuccal incision, and lower eyelid incisions.
Technique	■ Place IMF arch bars or screws, expose all the fractures adequately, disimpact the Le Fort III segment using Rowe forceps or perform osteotomies to reduce fractures anatomically, place the patient into IMF, align the zygomaticosphenoid sutures, and fixate at the zygomaticofrontal and nasofrontal buttresses as required.
Postoperative diet and care	■ Patients should be placed on a soft diet while in IMF, and use chlorhexidine mouthwash 3 times per day.

POSTOPERATIVE CARE

- Following fracture repair, resolution of facial edema may occur quite slowly. Therefore, postoperative airway compromise is of great concern. A tracheostomy may be considered preoperatively in severe clinical scenarios.
- Studies have demonstrated that Le Fort III type fractures, when compared to other facial fractures, are more likely to require a surgical airway.¹
- IMF is the most common cause of frustration in patients. Proper hardware management to improve patient compliance and comfort is necessary.
- During surgery and before discharge, intraoral wires should be examined to prevent irritation or pressure sores.
- Arch bar care should be initiated with the use of chlorhexidine mouthwash 3 times per day to prevent bacteria over-colonization.
- The patient should be placed on soft/puree diet until removal of arch bars. A scheduled antiemetic regimen can be useful as well.
- IMF should be kept in place for 1 to 3 weeks.² IMF can then be replaced with two elastic bands per side for a total of 6 weeks of treatment. Occlusion should be monitored throughout this period, and the patient should be placed

in IMF if malocclusion develops.

- At the end of the 6-week treatment, arch bars can be removed, and intraoperative assessment of occlusion can be performed at that time.
- Recently, several studies have examined the course of antibiotics needed after surgical management of facial fractures. All these studies have demonstrated that a short course of perioperative and postoperative antibiotics (less than 24 hours) is needed to prevent postoperative infections.^{3,4}
- Follow-up varies depending on surgeon preference. However, the patient should not be discharged from follow-up until at least 3 to 6 months postoperatively to allow adequate assessment of surrounding structures (ie, dental, ocular, or lacrimal system functions).

OUTCOMES

- Currently, there is a paucity of data exploring outcomes in patients with Le Fort III type fractures:
 - However, the handful of studies that have examined outcomes in this unique patient population indicate that Le Fort III type fractures are highly debilitating fractures that cause significant morbidity to patients.
- Bagheri et al.¹ examined over 60 patients with Le Fort I, II, and III types who presented to a single institution over a 13-year period.
 - They found that higher Le Fort injuries are associated with greater severity of trauma as measured by injury severity scores and have a more frequent need for surgical airways.
 - Additionally, Le Fort III type patients are more likely to require neurosurgical interventions and experience vision-threatening ocular trauma.
- Girotto et al.⁵ compared the long-term general health status and psychosocial well-being of patients who suffered Le Fort fractures to patients who presented to a general emergency ward:
 - These investigators found that increasing Le Fort complexity is associated with emotional problems and physical impairment secondary to altered social interaction as a result of the facial trauma.
 - Patients with increasingly complex Le Fort type fractures reported difficulties with vision, smell, mastication, breathing, and epiphora.
- These studies suggest that Le Fort III type fractures cause significant morbidity and limit patient's potential to achieve productive and active lives.

COMPLICATIONS

- Immediate complications after Le Fort type fractures involve airway compromise or bleeding:
 - High-energy facial trauma can result in significant soft tissue swelling that can obstruct the nasopharynx or oropharynx.
 - Deep or superficial vessel damage can occur secondary to high-energy maxillary fractures. Ligation or nasal packing can often control the bleeding, but manual reduction with IMF may also be needed.
- Subacute complications after Le Fort type fractures typically involve damage to the surrounding structures such as skull base (or cribriform plate) producing CSF leaks or lacrimal duct injuries causing orbital cellulitis or dacryocystitis.
- Infections are prone to occur in patients who present with facial soft tissue injuries and/or contaminated wounds. Although less common than mandibular fractures, infections can result in plate exposure and bone graft loss.
 - Infections can often be treated with antibiotics only. However, if associated with plate exposure or failure, plates and grafts may have to be removed.
- Nerve injuries can occur as well.
 - Forehead paresthesia can occur with injuries to the supraorbital nerve during retraction of the orbital tissue or during reduction and fixation of the medial or lateral orbital rims.
 - Weakness of the forehead or upper eyelid can occur with injuries to the frontal branch of the facial nerve. This often occurs when applying traction on the forehead flap.⁶
 - Blindness can occur following Le Fort II type fractures and results from severe swelling within the optic canal.⁷
- Nonunion or malunion are rare long-term complications following correction of Le Fort type fractures. They are often secondary to suboptimal surgical management (ie, fixation) or delayed treatment.
 - Facial asymmetries such as long vs short face, increased width, inappropriate projection, and malocclusion can occur following improper management.
 - If symptomatic, the fracture sites must be explored and corrected with possible osteotomies, bone grafts, plates, alloplastic or dental implants, or further orthognathic surgery.
- Plates can occasionally be visible or palpable in thin-skinned patients. This can be avoided by using low-profile plates or using interosseous wires.

Section XII: Panfacial Trauma

68 Maxillomandibular Fixation of Mandible Fractures

CHAPTER

Joseph Baylan and Dana Johns

DEFINITION

- Maxillomandibular fixation (MMF) can be used independently for closed reduction or in combination with open reduction and internal fixation (ORIF) for treatment of mandible fractures.

ANATOMY

- An understanding of dental anatomy and normal occlusal relationship is important when planning treatment with MMF.
- Incisor and canine teeth have a conical shape, whereas premolars and molars have a square shape.
- Normal occlusion is defined when the mesiobuccal cusp of the maxillary first molar occludes in the buccal groove of the mandibular first molar (**FIG 1**).
- The mandibular arch is lingual to maxillary arch.

PATHOGENESIS

- Two most common causes of mandible fractures are assault and motor vehicle collisions.
- Additional causes include gunshot wounds, falls, and sports injuries.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Focused history and physical examination
 - Mechanism of injury

- Full intraoral and dental examination
 - Evaluate for anterior or posterior open bite in centric occlusion.
 - Evaluate for dental trauma and overall state of dental health.
 - Evaluate areas of wear on the teeth (“wear facets”) to determine which teeth and where teeth made daily contact prior to the injury. These wear patterns can give an idea of preinjury occlusion, as the occlusion may not have been normal.

FIG 1 • Normal occlusion.

- Tips
 - Use tongue blade intraorally for complete soft tissue and dental evaluation.
 - Previous dental imaging and molds can be used to determine preinjury occlusion.

IMAGING

- Panorex plain films may be used to diagnose mandible fractures and can be used easily for postfracture follow-up.
- CT imaging is superior to plain films for diagnosing and evaluating mandibular fractures.
- Noncontrast maxillofacial CT, with 3D reconstruction if available, is useful for

determining fracture patterns, identifying concomitant injuries, and planning repair.^{1,2}

SURGICAL MANAGEMENT

■ Indications for MMF³:

- Temporary fragment stabilization as bridge to ORIF
- Conservative treatment
- Alveolar crest fractures
- Tension band in conjunction with rigid internal fixation
- Control of occlusion in the posttraumatic/postoperative period

Preoperative Planning

- Nutrition optimization is important for postoperative healing.
- For edentulous patients, consider intraoral prosthesis to maintain maxillary-mandibular relation.
- Appropriate preoperative evaluation of cardiopulmonary status is always indicated prior to any surgical procedure.
- Equipment
 - Erich arch bars and either 24- or 26-gauge dental wire (surgeon preference).
 - MMF set should include heavy needle drivers, wire cutting scissors, a pickle fork, and intraoral retractors (ie, Weider adult cheek tongue retractor, Minnesota, etc.).
 - Optional: MMF screws
- Anesthesia
 - General anesthesia via nasotracheal intubation is preferred.
 - Orotracheal intubation with ETT posterior to the retromolar trigone and submental intubation are other alternatives if nasotracheal intubation is not possible.
 - Tracheostomy should be performed if there are contraindications to the above-mentioned methods of anesthesia.

Positioning

- The patient is placed in the supine position with a shoulder roll and arms tucked.

TECHNIQUES

■ Arch Bars

- Check occlusion, paying attention to avulsed teeth and wear facets, to obtain preinjury occlusion.
- If possible, obtain prior dental records; however, this is often not possible in the acute trauma setting.
- Measure and cut appropriate length of arch bar required to span left second molar to right second molar.
- The arch bar should sit occlusal to the gingiva along the dental equator so as to avoid damage to the gingiva. Furthermore, the arch bar hooks should lie apical and symmetrical in the mandible and maxilla (**TECH FIG 1A**).
- A 24- or 26-gauge dental wire is passed around each side of the most distal molar with one end of the wire above and one end below the arch bar so that when the wire is twisted down it will secure the arch bar in place (**TECH FIG 1B,C**).
- Make sure the arch bar is correctly positioned prior to twisting the ends of the wire in a clockwise direction with a heavy needle driver:
 - Gently, pull up on the wire in a perpendicular direction to the arch bar during the twisting process to remove all slack from the wire. This is necessary to ensure the wire is tightened adequately.
 - Cut the wire, leaving 8 to 10 mm of the length to allow fold of the wire inward away from the gingiva, and place it along the arch bar to avoid gingival irritation.

TECH FIG 1 • A. Arch bar relationship to the teeth and gingiva. **B.** First step in application of arch bars. **C.** Completed application of arch bars.

- Apply wires to the next tooth in a sequential fashion to span the arch bar from left second molar to right second molar to prevent redundancy and possible malocclusion:
 - Wires are placed in the interproximal spaces and apical to the widest diameter of the crown.
 - Wires are placed around all molar and premolars due to stability of tooth roots.
 - Wires can be placed around the canines and incisors; however, recommendations are to include two teeth in each wire pass to disperse the force of the MMF over both teeth.
- After all wires are placed, check the stability of the arch bar by grabbing it with an empty needle driver and seeing if it can be mobilized in any direction:

- If the arch bar is mobile, check all wires for tightness, and add additional clockwise twisting as needed until the arch bar is immobile.
- MMF is achieved by taking a looped wire and placing it along a minimum of two hooks on each arch bar (upper and lower) and securing it in place with a twist knot in the clockwise direction. Tight dental elastics can be wrapped around upper and lower hooks and utilized for MMF instead of wire loops:
 - The benefit of elastics is ease of removal in case of emergent airway issues.
 - Their disadvantage is less rigid MMF, but this can be overcome with tight placement.

■ MMF Screws (TECH FIG 2)

- Primarily indicated in emergency cases, simple fracture patterns, and when standard arch bars cannot be applied.
- Contraindications include comminuted/displaced/unstable, mobile teeth, and children, if tooth buds are present at the planned location of screw placement.
- Check occlusion, paying attention to avulsed teeth and wear facets, to obtain preinjury occlusion. If possible, obtain prior dental records.
- The self-drilling and self-tapping screws are placed apical and in between the canine tooth roots of the maxilla and mandible bilaterally.
- Ensure screw head grooves are lying in same line to pass wire for MMF.
- A total of four screws are used, with two located on the mandible and two on the maxilla.
- MMF is achieved with 0.4 mm wires passed through head grooves on the screws in the maxilla and mandible and tightened in a clockwise direction with a heavy needle driver:
 - Repeat for contralateral side.

TECH FIG 2 • A,B. Placement of MMF wires. **C.** MMF screw in the mandible with wire loop to MMF screw in the maxilla (upper screw not shown). Wire is passed through channel in the screw head.

■ Rapid Fixation Hybrid MMF Systems

- Multiple rapid fixation hybrid MMF systems are available for use.
- These systems combine elements of both arch bars and MMF screws and can be used to secure patients in MMF.
- These systems are an additional option in patients with poor dentition.

■ Special Considerations in Edentulous Patients

- Fracture stabilization with existing dentures, Gunning splints, or MMF screws can be used in patients with edentulous mandibles.¹

PEARLS AND PITFALLS

Wire application

- Proper occlusion and fracture reduction must be established before complete tightening of the circumdental wires in the area of the fracture in order to prevent malreduction by the arch bar.
- When applying wires for arch bars, start in a sequential fashion from distal molar to distal molar. An alternative is to start mesial and work distally. This sequence prevents redundancy and possible malocclusion.
- When twisting wires to arch bar, start each strand length equidistant from the twist to the crown. This helps reduce wire fracture due to overtwisting.
- Wires generally change from shiny to dull color just prior to breakage. Learning to recognize the color change helps reduce wire fracture.
- While passing wires through the interproximal space during arch bar application, pay careful attention not to injure the gingiva. Also, care must be taken to prevent inadvertent needle injury to the surgeon.

POSTOPERATIVE CARE

- Patients will be on a full liquid diet and should have nutrition counseling and close monitoring of nutritional intake, with supplementation as needed.⁴
- Oral hygiene can be poor during MMF, and, therefore, Peridex mouth rinse is imperative in maintaining good oral hygiene.⁴
- Dental wax can be used to protect oral mucosa from injury by wires and arch bar hooks.
- Routine follow-up at 2 and 4 weeks after surgery to evaluate healing and assess occlusion.
- Wire fixation can be released at 2 weeks after surgery, and the patient can be transitioned to dental elastic band fixation for the remainder of MMF to permit early motion of the TMJ joint.^{2,4} If there is a concern for adequate healing, a panorex film can be obtained prior to switching from wire to dental elastic fixation.
- Fixation should be removed intraoperatively or 4 to 8 weeks postoperatively pending fracture healing.

COMPLICATIONS

- Overall, there is an increased risk of anesthetic complications in patients with mandible fractures who are treated with MMF compared to those who are not.⁵
- Additional complications include^{1,2,5}
 - Aspiration
 - Gingival trauma and recession
 - Difficulty with oral hygiene
 - Delayed temporomandibular joint mobility
 - Malocclusion⁶⁻⁸

ACKNOWLEDGMENTS

We would like to acknowledge Paul Mittermiller and Peter Lorenz in preparing this chapter.

69 Open Treatment of Mandible Fractures

CHAPTER

Joseph Baylan and H. Peter Lorenz

DEFINITION

- Mandible fractures are one of the most common facial bone fractures.
- Without adequate treatment, fractures of the mandible can lead to malocclusion, condylar resorption, and poor functional and cosmetic outcomes.¹

ANATOMY^{2,3}

- The mandible is a U-shaped bone composed of thick buccal and lingual cortices with a thin medullary canal.
- The mandible is divided into paired condyle, coronoid, ramus, angle, body, parasymphysis areas with a single midline symphysis, and tooth-bearing alveolus (**FIG 1**).
- Blood supply to the mandible comes from the inferior alveolar artery and direct muscular attachments.
- The inferior alveolar nerve traverses the mandible in the medullary canal, exiting at the mental foramen which is located inferior to the second premolar.
- Muscles inserting on the mandible (**FIG 2**):
 - Muscles of mastication
 - Masseter
 - Temporalis
 - Medial pterygoid
 - Lateral pterygoid:
 - Suprahyoid muscles
 - Digastric

- Stylohyoid
- Mylohyoid
- Geniohyoid

PATHOGENESIS

- Two most common causes of mandible fractures are assault and motor vehicle collisions.
- Additional causes include gunshot wounds, falls, and sports injuries.
- Most common location of fractures^{2,3}:
 - Condylar (36%)
 - Body (21%)
 - Angle (20%)
 - Symphysis (14%)
 - Alveolar ridge (3%)
 - Ramus (3%)
- Coronoid fractures (2%)
- Displacement of fracture segments commonly occurs from differing forces of inserting muscles³:
 - Muscles of mastication displace posterior segments superiorly.
 - Suprahyoid muscles displace anterior segment inferiorly.
- The lateral pterygoid displaces condylar head medially.
- Favorable mandible fractures³:
 - Nondisplaced by muscular pull.
- Most rami fractures.

FIG 1 • Bony anatomy of the mandible.

FIG 2 • Muscle attachments of the mandible.

■ Unfavorable mandible fractures³:

- Horizontal angle fractures that extend posteriorly and downward tend to be displaced by muscles of mastication.
- Vertical symphyseal and parasymphyseal fractures are displaced downward by suprahyoid muscles.
- High condylar fractures are displaced medially by the lateral pterygoid muscle.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Focused history and physical exam:
 - Mechanism of injury.
 - Full intraoral and dental examination.
 - Evaluate for anterior or posterior open bite in centric occlusion.
 - Evaluate for deviation of the mandible upon opening.
 - Palpate condyles in preauricular area and external auditory canal during opening to assess translation and tenderness.
 - Evaluate for mental nerve paresthesias.
 - Tips.
 - Use tongue blade intraorally for complete soft tissue evaluation.
 - Gingival lacerations are typically present at fracture sites.
 - Ecchymosis on the floor of the mouth is indicative of mandible fracture.
 - Chin deviation suggests condylar fracture.
 - Concomitant injury evaluation:
 - 2.6% of patients with facial fractures will have cervical spine injury.³

IMAGING

- Panorex plain films may be used to diagnose mandible fractures.
- CT imaging is superior to plain films for diagnosing and evaluating mandibular fractures.
- Noncontrast maxillofacial CT, with three-dimensional (3D) reconstruction if available, is useful for determining fracture patterns, identifying concomitant injuries, and planning repair.^{2,3}

NONOPERATIVE MANAGEMENT

- The majority of mandible fractures will require operative intervention.
- Nondisplaced, stable fractures with normal occlusion can be treated with soft diet and close follow-up.

- Greenstick-type fractures or minimally displaced fractures in children with normal occlusion can also be treated nonsurgically.^{3,4}
- In the case of edentulous mandibles, minimally displaced fractures can be treated nonoperatively.³

SURGICAL MANAGEMENT

- The main goal of operative intervention for mandible fractures is to restore preinjury occlusion and restore mandibular form and function.²
- Timing of surgery has no correlation to complication rates.^{2,5}
- Antibiotics:
 - All patients with mandible fractures should receive prophylactic antibiotics from the time of injury until the fracture is treated.
 - This practice has been shown to reduce postoperative infection from 50% to 6%.²
 - Penicillin-based antibiotic is preferred or clindamycin for patients with penicillin allergy.
- Postoperative antibiotics have been shown to have no effect on infection rates.²
- Fracture patterns to consider:
 - Symphysis and parasymphysis: fracture is located in the anterior mandibular portion between the canine teeth.
 - Body: fracture is located between canine and distal last molar.
 - Angle or ramus: fracture is located posterior to the second molar and triangle between the horizontal and ascending ramus and often involving the third molar.
- Condylar and subcondylar fracture: fracture is located superior to the ramus and is classified according to levels.
- Indications for open reduction and internal fixation (ORIF):
 - Severely displaced fractures
 - Bilateral fractures
 - Open fractures
 - Comminuted fractures
 - Multiple fracture sites
 - Panfacial fractures
 - Infected fractures
 - Uncooperative patients

- Patients with relative contraindication to MMF secondary to medical conditions (seizures, malnutrition, etc.)
- Indications for external fixation⁶:
 - Bridge until ORIF
 - Large segmental defect
 - Severe comminution
- Infection present
- Indications for removal of the teeth:
 - Grossly mobile teeth with periapical pathology or advanced periodontal disease
 - Teeth preventing fracture reduction
 - Fractured tooth root
 - Exposed root apices

Preoperative Planning

- Nutrition optimization is important for postoperative healing.
- For patients with edentulous mandibles, consider the creation of an intraoral prosthesis to help establish maxillary-mandibular relation.^{2,3}
- Appropriate preoperative evaluation of cardiopulmonary status is always indicated prior to any surgical procedure.
- Equipment:
 - MMF: Erich arch bars, 22- to 26-gauge wire.
 - Craniofacial mandibular plating system of preference. Different manufacturer's systems are similar, and vendors include Stryker, DePuy Synthes, and KLS Martin mandible plating sets. Choosing between systems is by surgeon preference, which is generally based on comfort/familiarity of use and availability at institution.
- Power bur and drill system.
- Anesthesia:
 - General anesthesia via nasotracheal intubation is preferred.
 - Orotracheal intubation with endotracheal tube (ETT) posterior to the retromolar trigone and submental intubation are other alternatives if nasotracheal intubation is not possible.
 - Tracheostomy should be performed if there are contraindications to the above-mentioned methods of anesthesia.

Positioning

- The patient is placed in the supine position with a shoulder roll and arms tucked.

TECHNIQUES

■ General Considerations

Fracture Exposure

- Local anesthetic with epinephrine should be injected into incision sites prior to making incisions.
- Begin with lower buccal sulcus incision over the area of the fracture leaving at least 10 to 15 mm gingival cuff at the unattached gingiva.
- Use existing extraoral lacerations for additional exposure if needed.
- Submental and submandibular approaches are alternatives to improve reduction and access for complex fractures of the body and angle.
- Expose fracture site in a subperiosteal plane paying careful attention to avoid injury to the mental nerve with wide exposure (**TECH FIG 1**).

TECH FIG 1 • Incisions for access.

Initial Approaches to Fracture Reduction

- Place patient in temporary MMF to help obtain preinjury occlusion.
- If fracture is displaced, manipulate segments until anatomic reduction is achieved.
- Consider the use of bone hooks or screws as adjuncts to achieve reduction.
- For comminuted fractures:
 - Realign fragments in a systematic fashion; superior to inferior, anterior to posterior, etc.
 - Temporary miniplates can be used to help hold reduction during realignment of fragments, but ensure plate location does not interfere with placement of reconstruction plate.
- Confirm mandibular condyles are seated.
- Ensure reduction is held with predrilled holes and reduction forceps placing clamps perpendicular to fracture line.
 - Alternative options include suture, wire, forceps, and an assistant.
 - The tendency is for splaying of the inner cortex of the mandible. Thus reduction is often applied with a medial force on the gonial angle in addition to a cephalad force to achieve reduction.

Plate Application (**TECH FIG 2**)

- Ensure the length of plate is adequate to span the fracture site and allow for a minimum of two screws on each side of the fracture site.
- Prior to plate application, confirm reduction is held appropriately and anatomically.
- Ensure mandibular condyles are well seated to prevent an anterior open bite.
- Plates should be contoured with plate bending pliers to fit flush with the underlying bone.
- Drill and insert the first screw without completely tightening it down for adjustment of plate position.
- Place the second screw on the other side of the fracture site, and then tighten the first screw completely.
- Fill remaining plate holes with screws.
- Consideration of a reconstruction plate may be necessary in cases of panfacial fractures or concomitant subcondylar fractures.
 - The superior border plate (tension band) will be monocortical to avoid

damage to the tooth roots.

- The inferior border plate (compression band) will be bicortical and often requires the use of a depth gauge to determine length of screw required.
- For comminuted fractures:
- Contour template to span the fracture and for flush placement of inferior mandibular border, paying careful attention to avoid injury to the mental nerve.
- Contour reconstruction plate using the template as a guide by torquing, in-plane bending, and out-of-plane bending, as necessary.
- Release MMF and ensure occlusion is appropriate. If concern for stability of fracture fixation is present, replace the patient in MMF with wires or dental rubber bands.

TECH FIG 2 • General plating technique.

■ Symphysis/Parasympysis

Nondisplaced and Simple Displaced Fractures

- The fracture should be stabilized with a minimum of two points of fixation.
- See general considerations for initial approaches to fracture reduction.
- After contouring, place two four-hole miniplates, 2.0 mm, at the fracture site, superiorly and inferiorly at the mandibular border.
- Apply monocortical screws below the apices of the tooth roots.
- Apply bicortical screws a few millimeters superior to the inferior border.
- See general considerations for plate application.

Comminuted Fractures

- The fracture should be stabilized with a minimum of two points of fixation.
- See general considerations for initial approaches to fracture reduction.
- Length of plate is dictated by a minimum of two screws on each side of the fracture to ensure load-bearing fixation.
- Mobile fragments can be held in place by screws through the reconstruction plate.
- Remove temporary plates if interference with reconstruction plate is present.
- Apply appropriate screws to reconstruction plate ensuring plate is flush with the mandible.
- See general considerations for plate application.

■ Body Fractures

Nondisplaced, Simple Displaced, and Oblique Fractures

- The fracture should be stabilized with a minimum of two points of fixation.
- See general considerations for initial approaches to fracture reduction.
- For nondisplaced fractures, place two four-hole 2.0-mm miniplates at the fracture site, superiorly and inferiorly at the mandibular border.
- For displaced and oblique fractures, place a 2.0-mm miniplate superiorly and a 2.4-mm compression plate inferiorly. An overbend of the compression plate is typically useful to ensure lingual cortex approximation at the fracture site.
- Apply monocortical screws below the apices of the tooth roots.
- Apply bicortical screws a few millimeters superior to the inferior border. To

protect the mental nerve, the plate must lie below the mental foramen. The use of retractors or transbuccal approach can ensure proper screw orientation.

- See general considerations for plate application.

Comminuted Fractures

- The fracture should be stabilized with a minimum of two points of fixation.
- See general considerations for initial approaches to fracture reduction
- Length of plate is dictated by a minimum of two screws on each side of the fracture to ensure load-bearing fixation.
- Mobile fragments can be held in place by screws through the reconstruction plate.
- Remove temporary plates if interference with reconstruction plate is present.
- Apply appropriate screws to reconstruction plate ensuring plate is flush with the mandible.
- See general considerations for plate application.

■ Angle and Ramus Fractures

Nondisplaced, Simple Displaced, and Oblique Fractures

- Consideration of plate placement should be either a plate along the external oblique ridge (Champy plate) or two miniplates along the superior and inferior border of the mandible.
- See general considerations for initial approaches to fracture reduction.
- Champy plate placement (**TECH FIG 3**):

TECH FIG 3 • Champy plate placed on the external oblique ridge of the mandible through intraoral approach.

- Plate should be twisted 90 degrees to sit flush with the superior border of the mandibular angle along the external oblique ridge.
- Apply monocortical screws below the apices of the tooth roots and place plate to sit flush against the underlying bone.
- Two miniplate placement (**TECH FIG 4**):
 - The superior miniplate can be contoured to sit along the external oblique ridge or along the superior border of the fracture.
 - After contouring, place a 2.0-mm miniplate superiorly with monocortical screws.
 - A stab incision is made on the skin overlying the fracture to allow for

transbuccal trocar devices.

- Apply bicortical screws a few millimeters superior to the inferior border.
- The first screw should be placed posterior to the fracture site through the transbuccal trocar.
- The second screw is then placed anterior to the fracture site through the transbuccal trocar ensuring adequate reduction.
- Remaining screws are then placed.
- See general considerations for plate application.
- Do not hesitate to make an additional skin incision to aid in fixation.

Comminuted Fractures

- See general considerations for initial approaches to fracture reduction.
- To fully realign fragments, transbuccal trocar devices can be used.
- Due to difficult location, a submandibular incision can be utilized by avoiding injury to the marginal mandibular branch of the facial nerve.
 - Incision is made 2 to 3 cm below the inferior border of the mandible.
 - Divide platysma muscle 2 to 3 cm below mandibular border, and dissect in a subplatysmal plane.
 - Below the mandibular border, the marginal mandibular branch lies anterior to the facial vessels in subplatysmal plane. Identify with the nerve stimulator or other nerve identification system.

TECH FIG 4 • Transbuccal trocar approach for inferior border plate.

- Identify and ligate facial vein, and retract vessel superiorly to also retract marginal mandibular branch.
- Divide pterygomasseteric sling, and incise the periosteum over the fracture site.
- Use temporary miniplates to help hold reduction during realignment of fragments, but ensure plate location does not interfere with placement of reconstruction plate.
- Mobile fragments can be held in place by screws through the reconstruction plate.
- Remove temporary plates if interference with reconstruction plate is present.
- Apply appropriate screws to reconstruction plate ensuring plate is flush with the mandible.
- Close pterygomasseteric sling and remaining layers of the wound.
- See general considerations for plate application.

■ **Condylar and Subcondylar Fractures**

- Condylar fracture lines are within the temporomandibular joint and capsule. Subcondylar fractures are located below the temporomandibular joint capsule.
- Subcondylar fractures are generally treated conservatively due to potential risk of necrosis of the condylar head from disruption of blood supply during open reduction repair. Furthermore, because of the location, application of plates and screws is difficult.
- Treatment primarily consists of MMF for a minimum of 2 weeks when nondislocated.

ORIF

- Absolute indications for ORIF: (a) displacement of the condyle into the middle cranial fossa; (b) difficulty in obtaining adequate occlusion by closed reduction; (c) lateral capsular displacement of the condyle; or (d) invasion of the condylar neck by a foreign body.⁷

- An intraoral approach can be considered with incision over ascending ramus, but this exposure can often be difficult to expose the fracture.
- A retromandibular, retroparotid approach is advocated for exposure of the condylar/subcondylar process. An alternative is a retromandibular, transparotid approach (**TECH FIGS 1 and 5**).

TECH FIG 5 • Retromandibular, retroparotid approach for exposure of the condylar/subcondylar process. An incision has been made through the SMAS and the parotid gland dissected off the masseter. The pterygomasseteric sling has been incised for subperiosteal access to the condylar/subcondylar process posteriorly.

- Incision is made from the mastoid process to the angle of the mandible. The use of local anesthetic with epinephrine may impair facial nerve function and limit the use of a nerve stimulator and nerve identification.

- An incision is made through the superficial musculoaponeurotic system, and the parotid gland is identified.
- Dissection is carried posteriorly, and the masseter is identified behind the parotid gland.
- The pterygomasseteric sling is incised, and a subperiosteal dissection is carried out to expose the area of fracture.
- See general considerations for initial approaches to fracture reduction.
- Manipulation of the fragment for reduction may also be achieved with the jaw open.
- Due to the lateral pterygoid forces, medialization of the condylar fragment occurs. This must be overcome by lateralizing the segment.
- A plate is then placed along the long axis of the fragment to hold the condylar segment in place, but the screw is not completely tightened.
- The mandible is pulled out to length in an anterior/inferior direction with reduction held by an assistant or bite block.
- With anterior traction applied to the plate, secure the remainder of the plate ensuring it is flush with the underlying bone.
- If possible, apply the second plate for fixation. However, this is often difficult due to limited exposure of the fracture.
- Close the pterygomasseteric sling and remaining layers of the wound.

■ Special Considerations

Fractures of Atrophic/Edentulous Mandible^{2,3}

- Often seen in patient with poor hygiene, malnutrition, immunosuppressed, and elderly.
- Closed reduction: achieved with wiring patients in dentures or Gunning-style splints, which are acrylic splints that take form of modified dentures.
- ORIF for displaced or comminuted fractures:
 - The procedure is often performed with a reconstruction plate through either a submandibular or intraoral approach. The extraoral approach is technically easier.
 - A locking plate must span from angle to angle with a minimum of two screws in all bone fragments. Generally, three or more screws are placed in all fragments, and all plate screw holes over intact bone are utilized due to

the poor bone stock.

- Screws are generally placed in the symphysis and angle due to better bone quality.
- Autogenous bone graft may be added to fracture site to facilitate healing as malunion/nonunion is common in these patients.
- External fixation: can be considered for temporary stabilization as a bridge until ORIF is possible.

External Fixation

- Approach considerations:
 - Observation indicated with significant comorbid medical conditions
 - Closed reduction achieved by wiring
- Application (**TECH FIG 6**):
 - Safe zones are located along lower and posterior portions of the mandible. Avoid the condylar neck so as to prevent damage to the facial nerve trunk. Other areas to avoid are the mental foramen and mandibular canal containing the inferior alveolar nerve.
 - Place patient in MMF to help align major fragments.
 - Via small stab incisions, blunt dissection to bone is performed.
 - Through a trocar, bicortical pins are placed with two pins through each major fragment.
 - Rods are placed at the two pins for each fragment followed by rod-to-rod clamps.
 - Achieve reduction and tighten rod-to-rod clamps.
 - Alternatively, a bow-shaped rod can attach directly to the pins.
 - Release MMF and check occlusion.

Coronoid Fractures

- Coronoid fractures account for less than 1% of all mandible fractures.
- They are often associated with zygomaticomaxillary fractures and can present as trismus.
- Fractures are often observed and managed with soft diet only.
- If persistent trismus or interference with mouth opening is present, coronoid removal is considered without significant sequelae.
- Consider ORIF vs removal in cases of panfacial fractures.

TECH FIG 6 • External fixation application technique.

PEARLS AND PITFALLS

Reduction	■ Insufficient reduction can lead to a higher rate of postoperative complications.
Fixation	■ Number of plates and screws should be limited, and avoid temptation to over treat with too large or too many plates. ■ Poor screw positioning can result in nerve or root damage. ■ Compression in comminuted areas should be avoided, and reconstruction plate should be used. ■ At least two screws should be placed on each side of defect for comminuted fractures.

POSTOPERATIVE CARE

- Adult patients who have undergone ORIF will be on a soft, nonchew diet for 4

weeks minimum.

- Patients who have been placed in MMF will be on a full liquid diet and should have nutrition counseling and close monitoring of nutritional intake, with supplementation as needed.⁶
- Peridex mouth rinse is imperative for maintaining good oral hygiene.⁶
- Routine follow-up at 2 and 4 weeks after surgery to evaluate healing and assess occlusion is recommended.
- Normal bony union takes 4 to 8 weeks, depending on the age of the patient.³
- Arch bars should be removed 4 to 6 weeks after surgery.

COMPLICATIONS

- Complication rates are directly related to the type of injury and location of fracture.^{1,3}
- Angle fractures have the highest rate of complications.^{1,3}
- Infection is the most common complication after repair of mandible fractures.¹⁻³
- Less common complications include³:
 - Nonunion.
 - Malunion.
 - Malocclusion.
 - Tooth loss.
 - Trismus.
 - Ankylosis.
- Broadening of the face especially with condylar and subcondylar fractures.
- Paralysis of marginal mandibular and/or mental nerves is generally transient.¹

70 Open Treatment of Condyle Fractures

CHAPTER

Michael A. Lypka

DEFINITION

- Condyle fractures of the mandible refer to a group of fractures involving the condylar head, neck, and base (**FIG 1**).¹
- There have been many classification schemes for mandibular condyle fractures; which classification system is best is debatable.
- Important concepts relating to complexity of surgical repair would be the cranial-caudal position of the fracture (condylar head fractures are complicated), medial or lateral displacement of the proximal segment relative to the ramus (medially displaced are more difficult), and degree of displacement of the proximal segment from the mandibular fossa.

ANATOMY

- Knowledge of the anatomy of the temporomandibular joint (TMJ) and surrounding structures is critical if open treatment of condyle fractures is entertained. The decision to operate must be balanced with the potential risks of surgery, most importantly the risk to the facial nerve (**FIG 2**).
- Temporomandibular joint (TMJ)
 - The TMJ is a symmetrically paired synovial articulation, which is the interface between the mandible and the base of skull.
 - The condylar head, with a lateral and medial pole, rests in the mandibular fossa, separated from the middle cranial fossa cephalad by a thin margin (approximately 1 mm) of bone. Anteriorly, the TMJ rests on the articular eminence of the zygomatic arch and translates along its slope with oral opening.
 - An ovoid biconcave avascular disk is interposed between the mandibular

condyle and temporal bone, separating the TMJ into superior and inferior joint spaces, in which translation and rotation occur, respectively. The superior head of the lateral pterygoid muscle inserts into the anterior aspect of the disk, whereas the inferior head inserts onto the mandibular condyle. The disk transitions into an innervated network of connective tissue and blood vessels posteriorly, known as the bilaminar zone.

FIG 1 • Classification of mandibular condyle fractures. The sigmoid notch line (Loukota's line) differentiates neck and base fractures. **A.** Condylar head fracture: fracture of the medial or lateral pole of the condyle. **B.** Condylar neck fracture: the fracture runs above the line for greater than half its length. **C.** Condylar base fracture runs below the line for greater than half its length.

- The joint capsule that surrounds the eminence and fossa blends with the periosteum of the zygomatic arch and condylar neck. It is thickened laterally to form the temporomandibular ligament or lateral ligament.
- Vascular/nerve supply
 - The external carotid artery bifurcates into two terminal branches within the parotid gland; the superficial temporal artery, which ascends vertically along the posterior border of the condyle and forms anterior and posterior branches above the zygomatic arch, and the maxillary artery, which traverses the condylar neck on its deep surface toward the pterygopalatine fossa.
 - The auriculotemporal nerve provides sensory innervation to portions of the auricle, external auditory canal, tympanic membrane, and temporal skin, and

runs parallel and posterior to the superficial temporal artery.

- The superficial temporal vein lies superficial and posterior to the artery and then drains into the retromandibular vein, which runs posterior to the ramus of the mandible.

FIG 2 • Complex anatomy overlying mandibular condyle.

- Parotid gland
 - The parotid gland, encapsulated by the parotidomasseteric fascia (parotid capsule), lies directly over the TMJ capsule.
 - The gland contains facial nerve branches coursing through it, as well as the superficial temporal artery and retromandibular vein.
- Relevant fascial layers (**FIG 3**).
 - Deep to the skin, in the temporal region, lies the temporoparietal fascia (TPF) or superficial temporal fascia. Anteriorly, this layer is continuous with galea/frontalis. The TPF is continuous caudally in the parotid region with the superficial musculoaponeurotic system (SMAS). In the neck, the SMAS is continuous with the platysma muscle.

- A layer deeper, in the temporal region, is the innominate or subgaleal fascia. The temporal branch of the facial nerve lies in this plane, deep to the TPF. The parotidomasseteric fascia in the parotid region is continuous with the innominate fascia above and the superficial layer of the deep cervical fascia in the neck. The marginal mandibular branch lies within or just deep to this cervical fascia.
- The temporalis fascia overlying the temporalis muscle, splits into superficial and deep layers above the zygomatic arch, containing the superficial temporal fat pad, before inserting onto the zygomatic arch.
- Facial nerve
 - The facial nerve emerges from the stylomastoid foramen and curves anteriorly into the parotid gland. It bifurcates within the parotid gland into temporofacial and cervicofacial branches, ultimately giving rise to five terminal branches: temporal, zygomatic, buccal, marginal mandibular, and cervical. There are many interconnections between buccal and zygomatic branches but not the temporal and marginal mandibular branches, thus requiring special attention during surgical exposures involving these branches.

FIG 3 • Relevant fascial layers in the area of the mandibular condyle.

- The temporal branch runs deep to the TPF, crosses the zygomatic arch, and lies anywhere from 8 to 35 mm anterior to the external auditory canal.²
- The marginal mandibular branch, of significance in the Risdon approach, lies in or deep to the superficial layer of the deep cervical fascia. It may course below the angle of the mandible (upwards of 1.2 cm). Anterior to the facial vessels, the marginal mandibular nerve is almost always above the inferior border.^{3,4}

PATHOGENESIS

- Condyle fractures are sustained from either an axial load or a lateral impact.
- A patient who sustains an impact to the chin transmits forces to the base of

the skull resulting in bilateral condyle fractures, often with a concurrent symphysis fracture.

- A lateral impact results in ipsilateral condyle fracture and concurrent contralateral body fractures.

NATURAL HISTORY

- Untreated condyle fractures typically will heal without treatment (meaning that bony union will occur), but sequelae such as malocclusion, TMJ pain, or rarely ankylosis (less than 0.5 per 1000)⁵ can occur.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The mechanism of injury should be ascertained. An impact to the chin, as in a fall directly onto the chin, should elicit suspicion for bilateral condylar fractures with possible symphyseal fracture. A lateral impact (punch to the face) may result in a condyle fracture on the side of impact.
- Change in occlusion, preauricular pain, concussive symptoms, and limitations of mouth opening are important historical data.
- Physical findings
 - Limited mouth opening: deviation to the side of fracture on opening
 - Change in occlusion
 - Premature molar contacts on the side of fracture or lateral open bite on the opposite side.
 - Anterior open bite in bilateral condyle fractures due to loss of vertical height
 - Occlusal canting
 - Facial asymmetry due to loss of height on the fractured side
 - Tenderness to palpation over the fracture sites in preauricular area

FIG 4 • **A.** Orthopantomogram of left condylar base fracture. **B.** Towne's view showing laterally displaced fracture. Coronal (**C**) and axial (**D**) CT scans of condylar head fractures in two different patients. (The author would not approach these surgically, although some would.) **E,F.** Sagittal CT sections of right and left condylar neck and base fractures. **G.** 3D CT scan of condylar base fracture.

- Blood in external auditory canal—signifies fracture of cartilaginous wall of EAC
- Submental lacerations
- Cervical spine tenderness (concomitant injury in approximately 5% of mandible fractures)

IMAGING

- Orthopantomogram is a useful x-ray that identifies most condyle fractures and provides an overview of teeth and bony structures, often giving additional information about occlusion (**FIG 4A**).
- Reverse Towne's view: This plain film, taken from posterior to anterior with the neck flexed, is a useful adjunct to the panorex to identify condyle fractures (**FIG 4B**).
- CT scans have become the standard for imaging of the maxillofacial skeleton in facial trauma and are indispensable in diagnosing and treatment planning for various types of condyle fractures.
- Coronal, axial, and sagittal views (**FIG 4C–F**), in addition to the 3D reconstruction (**FIG 4G**), will identify and characterize any fracture.

NONOPERATIVE MANAGEMENT

- In select cases with nondisplaced fractures on one or both sides, with a stable occlusion and limited pain, nonoperative management with a soft diet and progressive range of motion is appropriate.

SURGICAL MANAGEMENT

Indications/Contraindications

- According to Zide and Kent,⁶ absolute indications for open treatment include the following:
 - Displacement into the middle cranial fossa
 - Impossibility of obtaining adequate occlusion by closed reduction
 - Lateral extracapsular displacement
 - Invasion by foreign body
- The indications for open treatment of condyle fractures are relative, given the satisfactory outcomes of most fractures by closed means. Nonetheless, the decision to open condyle fractures is based on identifiable factors, including patient age, general health and mental state, concomitant panfacial fractures, and most importantly the surgeon's comfort level with opening condyle fractures. Common reasons for open treatment include the following:
 - Unilateral condylar fractures (fractures of the neck and base) with significant displacement or loss of vertical height
 - Bilateral condylar fractures (fractures of the neck and base) with significant displacement—to restore vertical height and projection

- Contraindications to open treatment include the following:
 - Condyle fractures in children
 - Fractures of the condylar head, including bilateral fractures. Although controversial, the author prefers managing postoperative malocclusions with orthognathic surgery rather than permanently disrupting the vascular supply to the condylar head, which often results in unsatisfactory results.

Preoperative Planning

- Combining history and physical findings, with a detailed radiographic evaluation, a decision is made to perform open reduction of the condyle fracture with the optimal surgical approach.

Positioning

- The patient should be positioned supine with the head in a horseshoe, allowing head rotation during surgery.

Approach

- There are three standard extraoral approaches to the mandibular ramus and condyle.
 - Retromandibular approach⁷ is the most used approach.
 - For fractures either just above, at, or below the sigmoid notch, this transparotid approach allows direct access to the fracture for efficient reduction and application of rigid fixation.

FIG 5 • Retromandibular incision relative to facial nerve branches.

- This approach is positioned between the buccal branches and the marginal mandibular branch, resulting in less traction on the nerve (**FIG 5**).
- Access is limited, however, because typically, only a small “window” can be created through the parotid gland.
- Risdon (submandibular)⁸ approach is the standard approach to the mandible.
 - This approach “from below” gives access to the entire ramus and condyle but requires significant soft tissue retraction, potentially resulting in traction injury to the marginal mandibular branch. A limited Risdon approach with the aid of an endoscope limits the need for extensive soft tissue retraction.⁹
 - Useful for fractures below the sigmoid notch or condylar head fractures in which a vertical ramus osteotomy is performed, and the condylar head disarticulated, with fixation of the segments on the back table and replacement with rigid fixation of the devascularized ramus/condylar unit (not advocated by this author).

- Preauricular approach allows access for condylar head fractures.
 - Access given by this approach is often too cephalad for most fractures and must be combined with another more inferior approach.
 - Useful to reduce a condyle fracture displaced into the middle cranial fossa.
- An intraoral approach to the condyle through a mandibular vestibular incision with or without endoscopic assistance, with extraoral trochar stabs or a special angled drill to apply fixation, is well described but will not be discussed here.¹⁰
- Open treatment of condyle fractures from an extraoral approach is already technically difficult, and it is the author's opinion that the intraoral-endoscopic technique, requiring special equipment and significant skill and training, should not be used by novice surgeons.

TECHNIQUES

■ Retromandibular Approach

Markings and Exposure

- Marking is made approximately a half centimeter below the earlobe paralleling the posterior border of the mandible, extending toward the angle (**TECH FIG 1**).
 - The incision can usually be limited to 2 to 3 cm.
- Local anesthetic with vasoconstrictor is administered. Avoid paralytic agents at this point so facial nerve monitoring is possible.
- The skin incision extends through the subcutaneous tissues and superficial musculoaponeurotic sling (platysma is thin in this region) to the parotid capsule.
- Vertical incision is made in the parotid capsule, entering the substance of the gland.
 - Blunt dissection is then performed through the gland, spreading in the direction of the facial nerve branches, in a horizontal or slightly oblique direction.
 - Toe-in retractors can be used to create a “window,” through the gland down to the mandible. Space is limited and will increase slightly with retraction. Typically, the window is between the buccal and marginal mandibular branches of the facial nerve. No attempt is made to isolate these branches,

but they may be encountered during dissection through the gland.

- Dissection through the pterygomasseteric sling is performed, with either a scalpel blade or Bovie cautery along the posterior border of the ramus. Subperiosteal dissection of the ramus, including the sigmoid notch and angle, then ensues, exposing the fracture cephalad.
- A toe-out retractor is placed behind the posterior ramus, protecting the retromandibular vein.
- A toe-in retractor is placed cephalad to locate the fracture line and displaced proximal segment.

Reduction and Fixation

- Fracture reduction is the difficult part.
 - Laterally displaced proximal segments, and those below the sigmoid notch, are the easiest to locate and reduce, whereas medially displaced, high condylar neck fractures are the most difficult.
 - Although not always feasible, it is best not to strip all the periosteal attachments from the proximal segment (dissect only the parts closest to the fracture site as necessary); otherwise, the segment will be devascularized, but more importantly, will become a floating target, making successful reduction difficult.
- Typically, the ramus has lost vertical height due to overlap of fracture segments. To re-establish height and achieve reduction, the angle of the mandible needs to be pulled caudally, thus stretching the sling. Paralytic agents may now be useful to accomplish this task.

TECH FIG 1 • Retromandibular incision preoperative marking (with mandible overlay).

- Two options exist to pull the angle caudally. A wire can be used to lasso a screw placed at the angle by using a spinal needle to enter the dissection pocket from below percutaneously. Another option is to open the posterior occlusion with a bite block. This may contaminate a sterile approach; however, external approach to the condyle is often combined with an intraoral approach if other fractures require reduction and fixation.
- Ideally, the fracture is reduced, and if stable, fixation is applied, with any one of three options: a four-hole plate at the posterior border; two plates, one at the posterior border and the other at the sigmoid notch; or a specifically designed plate for the condyle (**TECH FIG 2A–E**).
- Stable reduction prior to fixation is rarely achieved. Often, it is useful to apply the fixation plate with one screw in the proximal segment and use it as a handle to control the segment and reduce the fracture.
 - With the fracture reduced, another screw is placed in the distal segment, followed by the remaining screws.
 - Alternatively, a K-wire can be used as a joystick for the proximal segment to control its movement.

- After fracture reduction and fixation, the posterior border of the ramus should naturally flare posteriorly.
 - If it does not, re-evaluate fixation.
 - Check occlusion after reduction.
- Irrigate surgical site and begin closure.
- Repair of the pterygomasseteric sling can be attempted but is not performed by the author.
- The key to this approach is a watertight closure of the parotid capsule, to prevent sialocele formation.
- Skin closure is accomplished according to surgeon preference (**TECH FIG 2F**).

TECH FIG 2 • Three different options for fixation of the reduced condyle fracture: one four-hole plate (**A**), two plates (**B**), custom plate (**C**). **D,E**. Plate fixation through retromandibular approach. **F**. Typical postoperative appearance of scar.

■ Submandibular (Risdon) Approach

- Marking is made 1.5 to 2 cm below the inferior border of the mandible, either paralleling the inferior border of the mandible or following a natural skin crease of the neck (**TECH FIG 3**).
- If a natural skin crease is used, the incision will tend to diverge from the mandible anteriorly, requiring a longer incision for the same access relative to an incision paralleling the inferior border.
- Local anesthetic with vasoconstrictor is administered. Avoid paralytic agents so facial nerve monitoring is possible.
- Skin incision is made and dissection continues through the platysma muscle to the superficial layer of the deep cervical fascia. The marginal mandibular nerve is in this layer, or just deep to it.
- Blunt dissection continues through the deep cervical fascia over the submandibular gland but inferior to the inferior border of the mandible. A prominent lymph node (Node of Stahr) will be encountered, heralding the location of the facial artery and vein (artery lies anterior and deep to the vein).
- The artery and vein may be ligated at this time if exposure of the body of the mandible is necessary. The marginal mandibular nerve lies superficial to the vessels; if dissection ensues deep to them, the nerve is protected.
- With retraction of the soft tissue cephalad, an incision is made in the pterygomasseteric sling. Subperiosteal dissection of the ramus and condyle is performed with this approach.
- Fracture reduction and fixation ensues as described in the retromandibular approach. Direct access to the angle allows the mandible to be tractioned inferiorly by this approach. The fracture segments can be lag screwed via this approach.
- The pterygomasseteric sling is approximated, followed by the platysma, and skin layers.

TECH FIG 3 • Preoperative markings for preauricular and Risdon (submandibular approaches).

■ Preauricular Approach

Exposure

- The simplest approach is through the preauricular crease, extending from the superior helix to the lobule.
 - A cephalad extension can be made for improved access, either straight vertically into the hairline or anteriorly, in a hockey stick fashion, either at the anterior hairline junction or just above the junction.
 - Modification: Transitioning the marking along the margin of the tragus (endaural) is a common modification to conceal the incision. A retroauricular crease incision has been described but requires transection of the external auditory canal with later reapproximation (see **TECH FIG 3**).
- Local anesthetic is injected. Paralytic agents should be avoided, so facial nerve monitoring is possible.
- The skin incision proceeds through the TPF (cephalad) and SMAS

(caudally). If an endaural incision is used, avoid transecting the tragal cartilage after skin incision.

- The superficial temporal vein will be encountered first and ideally retracted anteriorly.
- Below the zygomatic arch, dissection proceeds along the border of the tragal cartilage or external auditory canal, in this avascular plane.
- If dissection proceeds too far anteriorly, away from the cartilage, the superficial temporal artery will be encountered.
- Bleeding from this source may be difficult to control.
- Above the zygomatic arch, dissection proceeds to the temporalis fascia.
- An oblique incision is made in the temporalis fascia, extending from the root of the zygomatic arch, exposing the superficial temporal fat pad.
- Veins within the fat pad, close to the area of dissection, may be cauterized with bipolar cautery.
- Inferiorly from this oblique incision, a periosteal incision is made on the root of the zygomatic arch, which transitions into the caudal dissection along the border of the external auditory canal.
- The zygomatic arch is exposed in a subperiosteal plane, unveiling the TMJ capsule below.
- The soft tissues are retracted anteriorly, protecting the temporal branch of the facial nerve, which is contained within the flap.
- A periosteal incision is made on the posterior border of the condylar neck; the joint space is not entered.
- A tunneling-type subperiosteal approach is then employed from above to access the condylar head and neck, exposing the sigmoid notch anteriorly. Remember that the main trunk of the facial nerve is just caudal to this area of dissection.
- This dissection can be connected with a subperiosteal dissection from an alternative approach (Risdon or retromandibular) from below (**TECH FIG 4**).

Reduction and Fixation

- The displaced fracture segments are located, reduced, and fixated. Hooks can be used to stabilize small fragments. Overly aggressive stripping of the periosteal attachments will devascularize bony segments and make fracture reduction more challenging.
- Condylar head fractures are usually fixated with small lag screws or

miniplates (1.5 or 2.0).

- Deep layer closure is not necessary in this approach, and skin closure can be performed based on surgeon preference.

TECH FIG 4 • Intraoperative view of exposure to TMJ.

PEARLS AND PITFALLS

Decision-making

- Select appropriate cases (evaluate CT scan carefully).
 - Fractures of the condylar neck and below
 - Avoid fractures in children and condylar head fractures.
- If not comfortable with regional anatomy, do not use an open approach.

Anesthesia

- Avoid paralytic agents in order to monitor facial nerve during dissection.
- Use paralytic agents after dissection is complete to facilitate fracture reduction.

Technique

- The posterior border of the ramus/condylar unit should curve gently posteriorly after reduction.
- Avoid excessive periosteal stripping to maintain blood supply and facilitate fracture reduction.
- Check occlusion after reduction and fixation.
- Assure good closure of parotid capsule to avoid sialocele formation in the retromandibular approach.

Postoperative care

- A short period of MMF or guiding elastics is a good idea to prevent occlusal disharmonies and avoid discomfort.

FIG 6 • A, B. Slight lateral posterior open bite due to loss of vertical height on the side of the fracture in a patient treated with a short period of maxillomandibular fixation. Patient refused open reduction.

POSTOPERATIVE CARE

- To avoid subtle occlusal discrepancies in the postoperative period (a result of swelling in the TMJ fossa from manipulation of the condyle), a short period (1 to 2 weeks) of maxillomandibular fixation or rubber band guidance is warranted.

OUTCOMES

- Most patients with condyle fractures, with either appropriate open or closed therapy, have excellent outcomes.
- The ability of the condyle to remodel and the stomatognathic system to adapt explain these good outcomes, even when the fracture is not reduced in closed treatment and when anatomic reduction is not precisely achieved in open

treatment.

- When treated ineffectively, however, certain sequelae may develop:
 - Malocclusion (most common) (**FIG 6**)
 - Long-term degenerative changes in the TMJ, with or without pain.
 - TMJ ankylosis (uncommon)—especially in the pediatric population when a fracture is unrecognized and range of motion is not established after the injury.
 - Iatrogenic facial nerve injury from open treatment approaches.

COMPLICATIONS

- Facial nerve injury. Typically, a traction injury resolves with time, but will be permanent if the nerve branches are transected or tractioned too aggressively.
- Poor scarring. Hypertrophic or unaesthetic scars are possible sequelae of extraoral approaches.
- Malocclusion. May be the result of:
 - Incorrect occlusion at fracture reduction
 - Improper fracture reduction (malunion)
 - Early failure of fixation
 - Loss of vertical height from resorption of the condylar head, leading to contralateral posterior open bite.
- Sialocele: Leakage of salivary fluid from parotid gland after the retromandibular approach. Prevented by careful closure of the parotid capsule. Treated with compression and antisialagogues.
- Malunion/nonunion
- Failure of fixation
- Facial widening/asymmetry

71 Management of Mandibular Coronoid Fractures

CHAPTER

Raja Naddaf

DEFINITION

- Mandibular coronoid process fracture is extremely uncommon. In the anatomical distribution of mandibular fractures, coronoid process fractures account only for 0.2% to 2% of all mandibular fractures.¹⁻³

PATHOGENESIS

- Etiology of coronoid fractures: motor vehicle accidents, interpersonal violence, sport injuries, and falls. Less commonly, fractures are caused during mandibular third molar extraction and bad split during mandibular sagittal split osteotomy.¹⁻³

ANATOMY

- The zygomatic arch protects the coronoid process along its lateral aspect. The temporalis muscle attaches to the lateral surface of the coronoid process.
- Fracture of the zygomatic arch with medial displacement of fragments can often impinge on the coronoid process of the mandible and cause trismus.^{1,3,4}

PATIENT HISTORY AND PHYSICAL FINDINGS

- Clinical exam demonstrates several symptoms, most commonly a limitation in mouth opening and in lateral movement of the mandible.
- In some cases, swelling and hematoma can be present; occlusion disturbance is less common and is usually related to other mandibular fractures.^{1,3,4}

IMAGING

- Plain radiographs or panoramic radiographs can be helpful, but the standard is computed tomography (CT) scans (**FIG 1**).

DIFFERENTIAL DIAGNOSIS

- Considering anatomical and functional relations, when facing a coronoid process fracture, the surgeon must take into consideration the probability of concomitant zygomatic arch fracture.

NONOPERATIVE MANAGEMENT

- Treatment of coronoid process fractures can be divided into three categories:
 - Nonoperative management
 - Conservative treatment
 - Open reduction and internal fixation (ORIF)
- Nonoperative management is advocated in cases of minimally displaced coronoid process fractures, absence of mouth opening limitation or trismus, and usually when the fracture is solitary.

SURGICAL MANAGEMENT

- In cases of concomitant zygomatic arch fractures, one should consider closed reduction of the arch fracture only.
- Several authors advocate the removal of the fractured coronoid process via an intraoral incision (coronoidectomy) in order to prevent fibrosis or ankylosis between the coronoid and the surrounding structures.^{1,3,4}
- ORIF is indicated in cases of significant displacement of the coronoid process or when there are other associated mandibular fractures (body, angle, condylar process).^{1,3,4}
- In cases of multiple mandibular fractures, there is an indication for ORIF of the coronoid fracture.

PREOPERATIVE PLANNING

- Imaging to visualize the coronoid fracture can be either x-rays, including panoramic radiography, or CT scans.

POSITIONING

- Nasal intubation is the preferred method, unless there are contraindications due to midface fractures or the need for tracheostomy.
- The patient should be placed in the supine position, with the head on a headrest to enable head manipulation during the operation.

APPROACH

- ORIF can be performed via an intraoral approach (less favored) or a modified

retromandibular approach or via submandibular approach through a Risdon incision (more favored).

FIG 1 • Coronoid fracture as shown on sagittal (A), coronal (B), and axial (C) CT scans. D. 3D reconstruction demonstrates a coronoid fracture with a concomitant zygomatic complex fracture.

TECHNIQUES

■ ORIF via Modified Retromandibular Approach

- Begin by marking the inferior border of the mandible.
 - The skin incision should be 2 cm inferior to the lower border of the mandible (or two fingerbreadths).
 - The lips should be exposed to see if the marginal mandibular nerve is stimulated during dissection.

- Vasoconstrictor with lidocaine can be injected subcutaneously but not deep to the platysma so the marginal mandibular branch is not anesthetized.
- The incision can be extended according to the location of the fracture. Posteriorly, it can be extended to the mastoid.
 - The incision is extended to the platysma. Then blunt dissection should be performed through the platysma and to the superficial layer of deep cervical fascia. This dissection should be extended to the full extent of the skin incision (**TECH FIG 1A,B**).
- Avoid injury to the marginal mandibular branch of the facial nerve, which is usually inferior to the lower border of the mandible and superficial to the facial artery and vein.
 - The facial artery and vein can be ligated, and once retracted superiorly, this ensures protection of the marginal mandibular branch (**TECH FIG 1C**).
- Continue the dissection until reaching the pterygomasseteric sling and then make a sharp incision through the sling.
 - Subperiosteal dissection is performed on the lateral surface of the body and ramus of the mandible and superiorly toward the coronoid process of the mandible (**TECH FIG 1D**).
- When exposing the fractured coronoid process, anatomical reduction and fixation is done by appropriate plates and screws.
 - Usually, two 2.0 miniplates are needed (conventional mandibular plates); when the reduction is gained, use a 1.5-mm drill and 2-mm screws.
 - At least two screws are required on each side of the fracture line.
 - In some cases, a single miniplate is sufficient to properly reduce the fracture.
- After completing ORIF, ensure hemostasis.
 - Close by approximating the pterygoid and the masseter muscles, preferably with continuous resorbable sutures.
 - Continue suturing the superficial layer of the deep cervical fascia and the platysma.
 - Close the skin incision with interrupted nylon sutures. These sutures are to be removed after 7 days.
 - Directions for wound care management are given prior to patient's discharge.

TECH FIG 1 • A. Hemostats have been used to bluntly dissect under the platysma. With the hemostats in place, the platysma is divided sharply. **B.** The marginal mandibular branch of the facial nerve is superficial to the facial artery and vein. **C.** After dissection through the superficial layer of the deep cervical fascia, the facial artery and vein are ligated and retracted superiorly. Then sharp dissection is performed on the pterygomasseteric sling. **D.** Subperiosteal dissection on the lateral surface of the body and ramus of the mandible and superiorly to the coronoid process.

■ Coronoidectomy by an Intraoral Approach

- Infiltrate lidocaine with vasoconstrictor.
- Make a vestibular incision through the mucosa, keeping a distance of 5 mm from the mucogingival line (**TECH FIG 2A**).

- Extend the incision to the external oblique ridge.
- Expose the ramus and the angle of the mandible with subperiosteal dissection (**TECH FIG 2B**).
 - The coronoid process is usually located in a more coronal position, because of persistent temporalis muscle attachments.
- After exposing part of the coronoid subperiosteally, grasp the coronoid with a large hemostat and pull while dissecting the coronoid subperiosteally until it is free from soft tissue.
- To close, suture the soft tissue with continuous resorbable sutures.

TECH FIG 2 • A. The vestibular incision is extended superiorly to the ascending ramus. **B.** Subperiosteal exposure of ascending ramus, lateral surface of the mandible, and the coronoid.

PEARLS AND PITFALLS

Physical findings

- Most coronoid fractures are treated conservatively.
- When a coronoid process fracture is present, consider the presence of associated zygomatic arch fractures, mandibular ramus, or body

	fractures.
Technique	■ A proper extraoral dissection using an electric nerve detector can aid in minimizing injury to the marginal mandibular branch of the facial nerve.
Postoperative	■ Short- or long-term limitation of mouth opening can be managed with physiotherapy.

POSTOPERATIVE CARE

- Antibiotics and corticosteroids can be administered.
- Soft diet should be given for the first few days after the operation.
- Chlorhexidine-containing mouthwash is used for 2 weeks.
- Postoperative panoramic and submentovertex x-rays can be performed postoperatively.
- If limitation of mouth opening is persistent 2 weeks postoperatively, the patient should receive physiotherapy.

OUTCOMES

- Patients with isolated coronoid fractures should generally have no long-term sequelae.
- Complications are much more likely to result from other associated facial fractures.

COMPLICATIONS

- Hematoma
- Limitation of mouth opening
- Trismus
- Wound infection
- Extraoral scars
- Malunion
- Nonunion
- Infection due to loose hardware
- Damage to the marginal mandibular branch of the facial nerve

72 Surgical Correction of Nonunion of Mandible Fracture

CHAPTER

Howard D. Wang, Arthur J. Nam, and Amir H. Dorafshar

DEFINITION

- Nonunion of a mandible fracture occurs when there is a failure of the fracture to heal within an adequate amount of time.
- Nonunion of a mandible fracture usually leads to pain, malocclusion, and inability to masticate.
- Haug and Schwimmer defined this time period as 8 weeks after surgical management or 4 weeks without treatment.¹
- Mandibular nonunions are uncommon complications after mandible fractures with a reported incidence of 2.8% to 3.9%.^{1–3}

ANATOMY

- The mandible consists of two hemimandibles fused at the midline symphysis, and injuries can be classified based on the location of the fracture.
- The most common location of nonunion is the body, followed by the angle region of the mandible.²

PATHOGENESIS

- Nonunion of mandible fractures generally occurs as a result of inadequate fracture stabilization, inaccurate reduction, infection, or delayed treatment.
- Other risk factors associated with nonunion include injury characteristics, such as teeth in the fracture line or presence of multiple mandible fractures, and patient characteristics such as edentulous mandible, tobacco use, alcohol abuse, immune deficiency, diabetes mellitus, or patient noncompliance.²

PATIENT HISTORY AND PHYSICAL FINDINGS

■ History

- A thorough history should include the patient's chief complaint and symptoms such as pain, trismus, fever, and drainage.
- Reviewing all preoperative, intraoperative, and postoperative data from previous surgical treatments related to the initial mandibular trauma is critical in identifying the etiology of nonunion.
- Patient comorbidities including diabetes mellitus, immunosuppression, or polysubstance abuse should be elicited as these factors can contribute to the ultimate outcome.

■ Physical examination

- Patient's facial height, width, and symmetry are assessed.
- The mandible is palpated for tenderness, bony deformities, presence of abscess, and instability.
- Intraoral examination is performed with a focus on the occlusion, dental decay, oral hygiene, presence of purulent drainage, and condition of the oral mucosa.
- Any existing deficits in the sensory distribution of the inferior alveolar nerve and motor innervation of marginal mandibular branch of facial nerve are documented.

IMAGING

- Plain x-ray films (facial series, panoramic) can be used for postoperative evaluation to identify an enlarging gap in the fracture line, presence of irregular radiolucency, and/or hardware loosening (**FIG 1A, B**).
- Maxillofacial computed tomography (CT) with three-dimensional formatting has become the imaging modality of choice for evaluation of the fracture site, extent of soft tissue infection, and associated osteomyelitis (**FIG 1C–F**).

NONOPERATIVE MANAGEMENT

- Mandibular nonunions are often associated with infections of the soft or bony tissue, which require antibiotic therapy.
- Choice of antibiotics should focus on coverage of Gram-positive and anaerobic organisms with subsequent culture-directed antibiotics.

FIG 1 • **A.** Immediate postoperative panoramic plain radiograph after ORIF of multiple mandible fractures. **B.** Follow-up panorex demonstrating hardware loosening and nonunion of the left mandibular angle fracture. **C.** A 3D reconstruction of CT images demonstrating right parasymphyseal fracture immediately after open reduction and internal fixation. **D.** Repeat CT imaging showing evidence of nonunion at 4 weeks after surgery. **E.** Soft tissue window revealing evidence of abscess

formation near the site of the nonunion. **F. Bone window** showing the presence of bone gap.

- The duration of treatment will depend on whether the infection affects the soft tissue alone or if osteomyelitis is present, which may require 4 to 6 weeks of intravenous treatment.

SURGICAL MANAGEMENT

- The general algorithm for management of nonunion of mandible fractures includes debridement of nonviable bone to establish fresh bony edges, bone grafting when there is a lack of bone-to-bone contact, and rigid fixation to achieve proper stabilization.
- Occlusion should first be established with maxillomandibular fixation (MMF). It is important to ensure that the condyles are well seated superiorly in the glenoid fossa.
- Although the presence of infection does not always necessitate removal of existing hardware, mandibular nonunions generally result due to inadequate stabilization, and existing hardware will usually need to be removed.
 - Any evidence of hardware loosening or fracture instability is a clear indication for hardware removal.
- Debridement of devitalized or infected bone back to healthy, bleeding bone is critical for both clearance of infection and achieving bony union.
 - Teeth in the line of fracture should be extracted, especially in the presence of infection.⁴
 - A bone biopsy should be performed to diagnose and guide treatment of osteomyelitis.
- Traditionally, management of infected mandibular nonunions was performed with prolonged MMF or external fixation to control occlusion while the infection is treated and the soft tissue is healing. This was done to avoid placement of hardware in an infected field.⁵
 - More recent work suggests that instability is a primary contributor to the development of infected mandible fractures and that the use of rigid internal fixation after adequate debridement is a viable treatment option to achieve resolution of infection and bony union.⁶
- Therefore, rigid internal fixation has become the preferred method and should be performed using a load-bearing reconstruction plate with at least three

bicortical locking screws on each side of the fracture.

- The closest screw should be placed at a minimal distance of 7 to 10 mm from the fracture edge.⁷
- If the bone gap is small, bony union can be achieved with improved rigid fixation. However, larger gaps with inadequate bone contact will require autogenous bone grafting.
- Cancellous bone grafts packed tightly into the defect area have a high success rate by improving osteogenic potential.⁸
- Vascularized bone flaps (with or without associated skin paddle) are indicated in cases where a critical-sized defect greater than 6 cm is present, when previous bone grafting has failed, or when severe soft tissue contracture is present.⁹
- Potential options include free fibula flap or deep circumflex iliac artery (DCIA) flap.
- The choice of donor site depends on the location and size of the mandibular defect.
- The DCIA flap is often preferred for mandible defects involving the dentoalveolar region because it provides ample bone stock for osteointegrated dental implants, and the fibula flap is preferred for long defects or when multiple osteotomies are required, such as for anterior mandible defects.¹⁰
- There are two schools of thought in terms of timing of reconstruction.
- The delayed approach involves treatment of infected mandible with long-term antibiotics (6 weeks) after debridement to allow for resolution of infection and healing of intraoral incisions and teeth extraction sites. Repeat imaging can then be obtained to ensure there is no evidence of infection. Autogenous bone grafting is then performed as a second stage.
- More recently, Alpert popularized the immediate approach in which autogenous bone graft is performed at the time of initial debridement.¹¹ The major advantage of this approach is avoiding a subsequent operation; however, soft tissue closure may be more challenging in these circumstances.

Preoperative Planning

- Careful review of imaging is performed to assess the need for teeth extraction and the extent of bony debridement.
- The need for autogenous bone graft or vascularized bone flaps is determined

prior to the operation.

Positioning

- The patient is positioned supine with nasotracheal intubation, so proper occlusion can be checked intraoperatively.
- If an iliac crest bone graft is needed, a bump should be placed under the gluteal region to elevate the iliac crest, and the lateral hip area should be prepped.

Approach

- Surgical management of mandibular nonunion can be performed via either an external transfacial approach or an intraoral approach.
- The major advantages of the intraoral approach are avoidance of an external scar and risk of injury to the marginal mandibular branch of the facial nerve.
 - However, the intraoral approach alone should be attempted only if there is sufficient healthy oral mucosa tissue for closure after debridement and fixation.
- Otherwise, an external approach is usually preferred after the intraoral wound has healed to avoid intraoral contamination of the surgical site. Furthermore, an external approach provides wide exposure for direct visualization of the fracture site, for obtaining sterile cultures, and for easier placement of bicortical screws while avoiding injury to the inferior alveolar nerve.
- The Risdon (submandibular) approach is frequently used to gain access to the body or angle region.

TECHNIQUES

■ Single-Stage Operation With Iliac Crest Bone Grafting via an Intraoral Approach

- Loose teeth within the fracture line are extracted (**TECH FIG 1A**).
- An intraoral incision is made to expose the fracture segment.
- Debridement of all nonviable bone is performed, usually with a cutting rotating bur.
- Patient's premorbid occlusion is then established with MMF.

- With the condyles seated properly in the glenoid fossa, the fracture segments are then placed into rigid fixation.
- In this case, a Champy plate and a lower border plate were applied (**TECH FIG 1B**).

TECH FIG 1 • A patient presented with a left mandibular angle fracture 4 weeks after initial injury. **A.** Maxillofacial CT demonstrating a nonunion of the left mandible angle fracture with the presence of a loose molar in the fracture line. **B.** Postoperative CT showing rigid fixation of the fracture with Champy plate and lower border plate. **C.** CT showing cancellous bone graft packed into the fracture gap.

- Three locking bicortical screws are inserted on each side of the fracture line to secure the lower border plate.
- Autogenous bone graft may be required in cases where a bone gap exists

after debridement of unhealthy bone at the site of the nonunion and can be harvested from a number of donor sites including the iliac crest, anterior tibia, or calvarium.

- The authors' preferred donor site is the iliac crest.
 - Once sufficient cancellous bone graft material has been harvested, it is packed tightly into the bone gap (**TECH FIG 1C**).
 - The intraoral incision is then closed tightly with absorbable sutures.
-

■ Two-Stage Operation With Osseous Free Flap

- The goal of the first stage is to remove all nonviable bone and allow healing of the intraoral soft tissue (**TECH FIG 2A**).
- Reconstruction of the mandible is performed in a subsequent operation via an external approach.

Stage 1: Debridement of Nonviable Bone and MMF

- Debridement of all nonviable bone is performed via an intraoral approach (**TECH FIG 3**).
- Patient's premorbid occlusion should be established with MMF.
- The intraoral wound is then allowed to heal over the course of 6 to 8 weeks.

Stage 2: Vascularized Free Osseous Flap Reconstruction via a Risdon Approach

- An osseous free flap such as the free fibula or DCIA flap may be required in cases when the size of the mandibular defect exceeds 6 cm.
- A two-team approach should be used whenever possible to reduce operative time.
- An external incision is made in a relaxed skin tension line approximately 2 cm caudal to the inferior border of the mandible. The length of the incision depends on the extent of the fracture (**TECH FIG 4A**).
- The platysma is divided after incision through the skin and the subcutaneous tissue (**TECH FIG 4B**).
- The marginal mandibular branch of the facial nerve lies deep to the platysma and may lie up to 2 cm below the ramus of the mandible; therefore, the platysma should be incised at least 2 to 3 cm below the inferior border of the mandible to avoid nerve injury.

TECH FIG 2 • A patient presented with nonunion of the left mandibular body fracture 8 weeks after open reduction and internal fixation at an outside facility. Because of the significant intraoral soft tissue deficiency, a two-stage treatment plan was selected. **A.** CT demonstrating evidence of nonunion of the left mandibular body after previous fixation. **B.** Exposed left mandible fracture with significant intraoral soft tissue deficiency.

TECH FIG 3 • Nonviable bone is removed using the existing intraoral exposure.

- The facial vessels lie deep to the marginal mandibular nerve in a craniocaudal direction. The vessels are ligated and reflected superiorly to protect the marginal mandibular nerve in the superior flap (**TECH FIG 4C**).
- The inferior border of the mandible is exposed by dividing the

pterygomasseteric sling and incising through the periosteum (**TECH FIG 4D**).

- Any unhealthy bone should be removed, and the fracture edges are burred until new bleeding edges are visualized (**TECH FIG 4E**).
- The recipient vessels should be identified in the neck for microvascular anastomosis. Options include the facial vessels, superior thyroid vessels, external carotid artery, and external and internal jugular veins.
- A DCIA flap is harvested along with a cuff of the internal oblique muscle (**TECH FIG 4F**).
- Once the flap has been harvested, a reconstruction plate is then adapted and applied to the bone flap.

A

B

C

D

E

F

TECH FIG 4 • A. Risdon (submandibular) approach to the mandible. The skin incision is made approximately 2 cm caudal to the inferior border of the mandible. **B.** The platysma muscle is then divided at 2 to 3 cm below the inferior border of the mandible. **C.** The facial artery and vein are identified and ligated. The marginal mandibular branch of the facial nerve runs superficial to the facial vessels. Reflecting the ligated facial vessels superiorly protects the nerve in the superior flap. **D.** Incision through the pterygomasseteric sling and the periosteum to expose the inferior border of the mandible. **E.** Excision of any remaining unhealthy bone. **F.** DCIA bone flap is harvested with a cuff of the internal oblique muscle. **G.** Flap inset into the defect and fixation with a reconstruction plate. **H.** Six-month postoperative CT demonstrating bony union.

- Flap inset is then performed with three locking screws placed on either side of the defect (**TECH FIG 4G**).
- Unicortical screws should be used on the flap to avoid injury to the vascular pedicle.
- Next, the microvascular anastomosis is performed to the recipient vessels.
- Closure of the incision should be performed in layers, approximating the pterygomasseteric sling, platysma, and skin. A suction drain can be left

depending on surgeon preference.

- Successful bony union can be seen on a follow-up CT scan (**TECH FIG 4H**).

PEARLS AND PITFALLS

Debridement	■ Aggressive debridement of pseudoarthrosis or infected bone stock is necessary for bony union.
Fixation	■ Rigid fixation with load-bearing construct is necessary to improve the chances of union.
Timing of bone grafting	■ Primary bone grafting can often be performed at the time of debridement. ■ If there is concern about the quality of soft tissue, bone grafting can be delayed and performed at a later stage.

POSTOPERATIVE CARE

- A 4 to 6-week course of postoperative antibiotics is usually administered for treating osteomyelitis.⁶
- The decision for use of postoperative MMF after rigid fixation is frequently surgeon-dependent.
 - Although some surgeons advocate that MMF is not required with rigid fixation, others prefer short-term (1 to 2 weeks) fixation with wires or elastics.
- The patient is started on a liquid or wired-jaw diet and progressed to a soft diet.
- Early physiotherapy is initiated to maintain maximum interincisal jaw opening and avoid complications of ankylosis of the temporomandibular joint.
- Patients with intraoral wounds are instructed to use chlorhexidine oral rinses at least 3 times a day.

OUTCOMES

- Studies on mandibular fracture nonunions are limited to small case series with short follow-up time.
- Benson and Alpert¹¹ retrospectively reviewed 43 patients with 50 infected mandibular fractures who were managed with debridement, rigid internal

fixation, and immediate autogenous particulate bone grafting.

- They reported that 94% achieved bony union and 86% required only one operation.
- Mehra et al.⁷ retrospectively reviewed 44 patients with infected mandibular fractures and divided them into those with soft tissue infection vs osteomyelitis.
 - Their treatment protocol of incision and drainage, debridement, fracture reduction, and stabilization with rigid internal fixation achieved 100% success rate for soft tissue–infected mandibular fractures and 92% success for those with osteomyelitis.
- Yamamoto et al.¹² reported that only 1 of 10 patients with mandible nonunion who were treated with removal of hardware and new fixation with 2.4-mm reconstruction plate required an additional operation to achieve union.

COMPLICATIONS

- Recurrent infection (ie, osteomyelitis)
- Nonunion
- Malunion
- Facial nerve injury (marginal mandibular branch) with external incision
- Inferior alveolar nerve injury
- Malocclusion
- Scarring
- Hardware exposure
- Trismus

Section XII: Panfacial Trauma

73 Surgical Correction of Panfacial Fractures

CHAPTER

Detlev Erdmann and David Powers

DEFINITION

- The facial skeleton is composed of four subunits: frontal, upper midface, lower midface, and mandible.
- Panfacial fractures are defined as any fracture pattern that involves at least three of these four segments.¹

ANATOMY

- The face consists of 14 bones, 12 of which are paired (inferior nasal concha, lacrimal bones, nasal bones, maxillae, palatine bones, zygomatic bones) and 2 of which are not (mandible and vomer).
- The frontal bone constitutes the major component of the forehead and forms the superior part of each orbital rim.
- Zygomatic process of the frontal bone projects inferiorly to form the upper lateral orbital rim.
- The zygomatic bone forms the lower lateral and part of the inferior orbital rim.
 - Malar surface: Convex shape, contains the zygomaticofacial foramen
 - Temporal surface: Concave, articulates with maxilla (articular surface) and contains the zygomaticotemporal foramen
 - Orbital surface: Contains the zygomatic orbital foramen
- The nasal bones articulate with each other at midline as well as the frontal bone superiorly and the frontal process of the maxillary bone laterally.

- Maxillae lie in between the orbit and the upper teeth and consist of a body, zygomatic process, frontal process, alveolar process (contains the teeth of the upper jaw), palatine process (forms 75% of the hard palate), infraorbital foramen, and maxillary sinus.
 - Forms the inferior and medial orbital rims
 - Articulates with the frontal, zygomatic, ethmoid, nasal, and lacrimal bones
- The mandible consists of a body (anterior) and ramus (posterior).
 - The body of the mandible is further subdivided into the base and the alveolar portion, which contains the teeth of the lower jaw.
 - The ramus consists of two clinically significant superior projections:
 - The more posterior projection is called the condyle (which contributes to the formation of the temporomandibular joint).
 - The more anterior projection is called the coronoid process (which is the site of attachment for the temporalis muscle).

PATHOGENESIS

- Facial fractures occur in the setting of trauma, with assault and motor vehicle collisions (MVC) as the most common etiologies (36% and 32%, respectively, of all facial fracture cases presenting to a representative US institution).¹
- MVC and gunshot wounds (GSW) have been specifically shown to be significant predictors of panfacial fracture patterns.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- Once the patient has been appropriately stabilized, obtaining as complete a history as possible is integral to assess for specific injury patterns even prior to performing imaging studies.
- The following questions are most important when performing a systematic exam of the patient:
 - How and when did the accident occur?
 - What are the specifics of the injury?
 - What symptoms does the patient currently have (pain, altered sensorium, loss of consciousness, malocclusion)?
- Certain subjective complaints can substantiate the presence of specific craniomaxillofacial injuries; for example, new-onset anesthesia of the cheek/maxillary teeth may be a result of zygomaticomaxillary fractures resulting in injury of the infraorbital nerve.
- Physical examination

- Cranium/cranial base: Note any lacerations, swelling, ecchymoses, and contour irregularities.
- Frontal region: Inspect for any lacerations, depressions, or crepitus.
- Orbits: Examine for edema, ecchymoses, enophthalmos (possible zygomaticomaxillary complex fractures), emphysema, and limited upward gaze (possible inferior rectus muscle entrapment).
- Nasal region: Check for signs of naso-orbital-ethmoid (NOE) fracture, such as septal deviation or hematoma and telecanthus.
- Maxillary region: Assess for infraorbital nerve paresthesia or malar depression, trismus secondary to impingement on the coronoid process, and maxillary mobility.
- Ear region: Examine for hematoma and integrity of auditory canal/tympanic membrane.
- Mandible: Note the presence of external lacerations, ecchymosis or gingival tears (a possible sign of mandibular body or symphyseal fracture), step-off deformities, paresthesia along the distribution of the inferior alveolar nerve (an indication of fractures distal to mandibular foramen), periauricular pain, or malocclusions.
- Additionally, a thorough intraoral, ocular, and neurological exam should be conducted to rule out dental malocclusions, ophthalmological emergencies, and focal neurological defects.

IMAGING

- Computed tomography (CT) has largely replaced other imaging modalities as the standard for evaluation of facial trauma.
- Axial, coronal, and sagittal cuts are utilized to visualize specific fracture patterns and reformatted to generate three-dimensional (3D) images (**FIG 1A–C**).
- A standard head CT is better used as a screening tool, given its limited ability to visualize the zygomatic arch as well as the complete maxilla and mandible (**FIG 1D,E**).
- A more complete craniomaxillofacial CT should extend from the vertex of the skull to the symphysis of the mandible.
- 3D CT imaging affords additional understanding of the spatial relationship of fracture fragments but does not provide information about soft tissue deformities.

NONOPERATIVE MANAGEMENT

- Although most panfacial fractures are severe enough to warrant surgical treatment, facial fractures that are stable, nondisplaced, or asymptomatic may be managed conservatively with follow-up.²

FIG 1 • **A.** Axial CT imaging can be used to visualize specific fracture patterns. **B,C.** CT imaging can be reformatted into three-dimensional images that are useful for preoperative planning. **D.** Craniomaxillofacial CT imaging provides a more comprehensive view of the zygomatic arch as well as the maxilla and mandible. **E.** Comminuted midface fractures.

SURGICAL MANAGEMENT

- The primary goal of panfacial trauma management is to establish an anatomically reduced platform from which to base the remainder of the reconstruction.

Preoperative Planning

- Review of preoperative radiographs with 3D reconstruction is necessary.
- Written sequencing of surgical approaches and goals for each section
- Confirmation of necessary surgical instrumentation and plating hardware to reconstruct the defects

Positioning

- The patient should be prepared and draped widely to allow for any and all needed exposures.
- A horseshoe head frame may be used for coronal exposure.

Approach

- One of the more common techniques for addressing midfacial fractures, often referred to as “outside-in” technique, focuses on first repairing the zygomatic arch to correct facial width.
- Zygomaticomaxillary complex fractures are usually repaired with open reduction and internal fixation.³
- The “bottom-to-top” approach focuses on reconstruction of the mandible first—generally accomplished as the mandibular bone is less prone to comminution in most causes of panfacial trauma—which results in larger bone fragments that are technically easier to repair.
- The “top-to-bottom” approach initiates repair at the forehead before working down to the maxilla and mandible (**FIG 2**).
 - This approach focuses on reconstruction of the “outer facial frame.” The orbital rims are used as a landmark to align the nasofrontal structure before reduction of the zygomatic arches and realignment of the maxilla and mandible.^{4,5}
- The “bottom-to-top-to-middle” approach focuses on reconstruction of the mandible first—generally accomplished first because the mandibular bone is less prone to comminution in most etiologies of panfacial trauma—which results in larger bone fragments that are technically easier to repair.
 - Attention is then directed toward the zygomatic arches/frontal bar regions and the NOE/orbit, correcting any discrepancy at the Le Fort I level as the final intervention.
- Possible incisions for gaining access to the mandible include the following:
 - Anterior degloving (**FIG 3A**)

- Intraoral degloving (**FIG 3B**)
- Posterior degloving (**FIG 3C**)
- Hinds incision/posterior ramus approach (**FIG 4**)
- Preauricular incision (**FIG 5**)
- Risdon incision (**FIG 6**)
- Submental incision (**FIG 7**)
- Transcervical incision (**FIG 8**)

FIG 2 • The “outside-in” technique focuses on repairing the zygomatic arch first in order to correct facial width.

FIG 3 • Anterior (A), intraoral (B), and posterior (C) degloving incisions are made about 3 to 5 mm above the mucogingival junction and carried down through the mucosa, submucosa, facial muscles, and periosteum.

FIG 4 • The Hinds incision is particularly helpful for injuries involving the ramus, neck, or head of the mandible. Avoid the superior and inferior divisions of the facial nerve as well as the retromandibular vein. The incision can be made parallel to the ramus or over the posterior border of the ramus toward the mandibular angle.

FIG 5 • Preauricular incisions can be utilized to expose the TMJ. Given the location of the superficial temporal vessels and the auriculotemporal nerve relative to the TMJ, injury to these structures is possible and must be avoided. The incision is made to the superficial layer of the temporalis fascia. An anterior flap is then raised above the zygomatic arch and the superficial layer of the temporalis fascia is incised. The periosteal elevator is then shifted posteriorly and incised vertically. Retraction will then expose the TMJ capsule.

FIG 6 • **A.** The Risdon incision can be used to expose the mandibular angle, ramus, condyle, and TMJ. The incision is made 2 cm inferior and parallel to the inferior border of the mandible of the neck and to the level of

the platysma. **B.** Dissection is continued to the deep cervical fascia and submandibular salivary gland, with eventual incision of the superficial layer of the deep cervical fascia. Great care must be taken to avoid injury to the facial artery and vein as well as the marginal mandibular branch of the facial nerve. **C.** During anterior dissection, the mental nerve must be avoided.

FIG 7 • The submental incision, used in repair of mandibular symphysis fractures, can be made to follow the anterior curve of the mandible or can be hidden within a skin crease. The incision is made to the platysma. Dissection is carried out to the inferior border of the mandible and the periosteum is incised sharply.

FIG 8 • A. The transcervical incision is made above the thyroid cartilage from the midline toward the angle of the mandible bilaterally and carried down to the superficial layer of the deep cervical fascia. **B.** A flap is then raised toward the inferior border of the mandible anterolaterally. Identify the cervical and mandibular branches of the facial nerve as well as the facial artery and vein to avoid injury. The periosteum is then incised at the inferior border of the mandible from midline to the mandibular angle bilaterally.

TECHNIQUES

■ Bottom-to-Top Approach

- Erich arch bars are adapted to the maxilla and mandible and secured with 24-gauge stainless steel wires.

Video p2-c073_01

- Placement of the arch bars should only begin on one side and progress laterally by incorporating all of the dentition.
- The arch bars are malleable, and simultaneous placement of the arch bars from the bilateral posterior region results in “excess” material, which classically prevents incorporation of the anterior dentition.
- Bone-anchored arch bars can be considered for dental arches that do have? disruption of the dentoalveolar tables (**TECH FIG 1A,B**).

TECH FIG 1 • A. Preoperative appearance. **B.** Arch bar placement. **C.** Resuspension of soft tissue. **D.** Closure of incisions.

- Access to the mandible is achieved with a combination of a no. 15 scalpel (see **FIGS 3 to 8**) and Colorado-tipped Bovie electrocautery to address the regions of the mandible requiring fixation.
- Anatomically reduce and stabilize the mandible with the appropriately sized surgical reconstruction kit placed in a bicortical manner to avoid vital structures.
 - The use of monocortical screws and a “simplification” plate may be necessary to assist with temporary stabilization of the mandibular fracture.
 - Impressions for dental splints should be accomplished only after the establishment of a stable dentoalveolar table of at least one dental arch.
- Access to the maxilla is achieved with a combination of a no. 15 scalpel and Colorado-tipped Bovie electrocautery.
 - The incision is made approximately 5 to 7 mm superior to the junction of the attached gingiva and alveolar mucosa to reduce maxillary fractures for the establishment of a functional occlusion.
- The patient’s occlusion is established with intermaxillary/maxillomandibular

fixation.

- Stabilization of the maxillary fractures is then performed.
- A coronal incision is performed with a no. 15 scalpel and Colorado-tipped Bovie electrocautery to gain access to the zygomatic arches/frontal bar bilaterally.

Video p2-c073_02

Video p2-c073_03

- Reduction/stabilization of the zygomatic arch fractures is accomplished, as well as any frontal bar/frontal sinus fractures.

Video p2-c073_04

- Repair of orbital floor fractures is accomplished.
- Repair of NOE fractures is accomplished.
- Intraoperative CT scanning (if available) is obtained at this time to evaluate reduction and fixation.
- Facial soft tissues are resuspended (**TECH FIG 1C**).
- Closure of incisions (**TECH FIG 1D**)

■ Top-to-Bottom Approach

- A coronal incision is performed with a no. 15 scalpel and Colorado-tipped Bovie electrocautery to gain access to the zygomatic arches and frontal bar bilaterally.
- Reduction with stabilization of the zygomatic arch, zygoma, and any frontal bar and frontal sinus fractures is completed.
- Repair of NOE fractures is accomplished.
- Repair of orbital floor fractures is performed.
- Erich arch bars are adapted to the maxilla and mandible and secured with 24-gauge stainless steel wires.
 - Placement of the arch bars should begin on one side and progress laterally, incorporating all of the dentition.
 - The arch bars are malleable, and simultaneous placement of the arch bars from the bilateral posterior region results in “excess” material, which classically prevents incorporation of the anterior dentition.

- Bone-anchored arch bars can be considered for dental arches that do not have disruption of the dentoalveolar tables.
- Access to the mandible is achieved with a combination of a no. 15 scalpel and Colorado-tipped Bovie electrocautery to address the regions of the mandible requiring fixation (see **FIGS 3 to 8**).
- Anatomically reduce and stabilize the mandible with the appropriate-sized surgical reconstruction kit placed preferably in a bicortical manner to avoid vital structures.
 - The use of monocortical screws and a “simplification” plate may be necessary to assist with temporary stabilization of the mandibular fracture.
 - Impressions for dental splints should be accomplished only after the establishment of a stable dentoalveolar table of at least one dental arch.
- Access to the maxilla is achieved with a combination of a no. 15 scalpel and Colorado-tipped Bovie electrocautery via an incision approximately 5 to 7 mm superior to the junction of the attached gingiva and alveolar mucosa.
 - This is to address the regions of the maxilla requiring reduction of maxillary fractures for establishing a functional occlusion.
- The patient’s occlusion is established with intermaxillary/maxillomandibular fixation.
- Stabilization of the maxillary level fractures is performed.
- Intraoperative CT scanning (if available) is obtained at this time to evaluate reduction/fixation.
- Facial soft tissues are resuspended.
- Closure of incisions

■ Bottom-to-Top-to-Middle Approach

- Erich arch bars are adapted to the maxilla and mandible and secured with 24-gauge stainless steel wires.
 - Placement of the arch bars should only begin on one side and progress laterally incorporating all of the dentition.
 - The arch bars are malleable, and simultaneous placement of the arch bars from the bilateral posterior region results in “excess” material that classically prevents incorporation of the anterior dentition.
 - Bone-anchored arch bars can be considered for dental arches that do not have disruption of the dentoalveolar tables.

- A no.15 scalpel and Colorado-tipped Bovie electrocautery can be used to access the regions of the mandible requiring fixation (see **FIGS 3 to 8**).
- Anatomically reduce/stabilize the mandible with the appropriate sized surgical reconstruction kit placed preferably in a bicortical manner should this avoid vital structures.
 - The use of monocortical screws and a “simplification” plate may be necessary to assist with temporary stabilization of the mandibular fracture.
 - Impressions for dental splints should be accomplished only after the establishment of a stable dentoalveolar table of at least one dental arch.
- Access to the maxilla is achieved with a combination of a no. 15 scalpel and Colorado-tipped Bovie electrocautery via an incision approximately 5 to 7 mm superior to the junction of the attached gingiva and alveolar mucosa. This treats the regions of the maxilla requiring reduction of maxillary fractures for the establishment of a functional occlusion.
- The patient’s occlusion is established with intermaxillary/maxillomandibular fixation.
- A coronal incision is performed with a no. 15 scalpel and Colorado-tipped Bovie electrocautery to gain access to the zygomatic arches/frontal bar region bilaterally.
- Reduction/stabilization of the zygomatic arch fractures is accomplished, as well as any frontal bar/frontal sinus fractures.
- Repair of orbital fractures is accomplished.
- Repair of NOE fractures is accomplished.
- Maxillary level fractures are stabilized.
- Intraoperative CT scanning (if available) is obtained at this time to evaluate reduction/fixation.
- Facial soft tissues are resuspended.
- Layered closure is undertaken, including interrupted absorbable suture material for deep and dermal layers and nonabsorbable interrupted closure for skin.

PEARLS AND PITFALLS

Preoperative radiology

- Comprehensive CT scans with 3D reconstruction

	should be obtained for presurgical planning on all panfacial trauma patients.
Exposure	■ Adequate exposure for visualization of all fractures is critical for anatomic reduction.
Subunit principle of repair	■ Repair the cranio-orbital subunit independent of the lower face and the maxillomandibular subunit independent of the upper face.
Ptosis of soft tissues	■ Lack of resuspension of the facial soft tissues after skeletonizing the calvarium for access to the fractures results in ptosis of the fat pads of the face and premature facial aging.
Reliance on dental splints without a stable skeletal foundation (either anatomically reduced maxilla/mandible)	■ Because of normal variability in dental occlusion, the lack of a stable arch form for reconstruction frequently results in loss of AP projection of the face and the classic appearance of a flat, wide midface.
Interval/intraoperative CT scans	■ Critically determine the proper alignment and stabilization of the facial structures during complex reconstruction.
Postoperative review of radiology	■ 3D CT scans should be evaluated in the immediate postoperative period to determine the need for potential early intervention to correct issues of enophthalmos, inadequate reduction, or poor stabilization.

FIG 9 • Postoperative review of midfacial **(A)** and mandibular **(B)** reconstruction.

POSTOPERATIVE CARE

- If intraoperative CT scanning was not accomplished to review the reduction and fixation of fractures, comprehensive radiographic evaluation is performed in the immediate postoperative period in order to determine any potential need for revision (**FIG 9**).
- Daily checks are necessary while the patient is hospitalized; weekly outpatient checks should be performed until intermaxillary/maxillomandibular fixation has been discontinued and arch bars have been removed. Continue to reinforce the importance of oral hygiene.
- Physical therapy for active range of motion is frequently needed.
- Upon optimization of skeletal alignment and scar maturation (typically after 1 year), revision of soft tissue injuries may be undertaken.

OUTCOMES

- Gutta et al.⁶ performed a 5-year analysis of postoperative outcomes in patients who received treatment for mandibular fractures:
 - In a cohort of 363 patients, the overall complication rate was 26%, with hardware failure and infection being the two most common complications.

- Patel et al.⁷ found that methods of fixation, such as the Champy technique and use of reconstruction plates, were associated with higher rates of bony union and patient comfort.
- Extraction vs retention of teeth in the line of fracture has not been shown to significantly impact the outcome of reconstruction.
- A critical review of the literature, coupled with an internal review of more than 1200 facial fracture cases managed at our institution over a 6-year period, suggests that most complications encountered are secondary to operator error, either in decision-making/judgment or in technical performance.
- Rigidly stabilizing a fracture in a nonanatomic position resulting in malocclusion is not a failure of the hardware, nor should the surgeon expect the malocclusion to spontaneously correct.
- Selecting an inappropriate type/size of surgical plate for fracture repair without an understanding of the functional load the plate is subjected to should not be considered hardware failure if the plate loosens or breaks.
- Inadequate intraoral/extraoral closure of the surgical access or wound, with resulting exposure of the surgical hardware, is not truly a hardware complication.⁸
- In a single-center retrospective review of 359 patients who underwent surgical management of facial fractures, specific mechanisms of injury (such as MVC) and concomitant tobacco, alcohol, and/or tobacco use were associated with higher rates of surgical site infections.⁹

COMPLICATIONS

- Nonunion
- Malocclusion
- Asymmetry/soft tissue ptosis
- Soft tissue scarring
- Narrowing or overwidening of the face
- Lid malposition

ACKNOWLEDGMENT

We thank Visakha Suresh, BSE, BS, for her valuable contribution to the preparation of this chapter.

CHAPTER Pediatric Orbital Fractures

James Y. Liao

DEFINITION

- Fractures of the inferior and/or medial orbital wall

ANATOMY

- The orbit consists of seven bones; however, the ones that are involved are invariably the maxilla and ethmoid bones. Operative repair focuses on re-establishing the appropriate volume of these components (**FIG 1A**).
- Other pertinent anatomy includes optic nerve and superior fissure, which contains CN III to CN VI. These structures are located in the superior medial aspect of the orbit (**FIG 1B**).
- Soft tissue anatomy is relevant. This includes the palpebral fissure, gray lash line, septum, canthus, and caruncula (**FIG 1C**).
- Usually, orbital growth is complete by 6 to 8 years of age.

PATHOGENESIS

- Inferior orbital floor fractures occur with facial trauma, which entails a blow to the globe resulting in increased orbital pressure. This pressure fractures the thinner maxillary portion of the orbital floor causing a blow-out fracture into the maxillary sinus.

NATURAL HISTORY

- Diplopia that is self-limiting
- Enophthalmos can occur if the orbital volume is not corrected with floor reconstruction or soft tissue volume atrophy from trauma.

- Entrapment results in muscle fibrosis and permanently impaired conjugate gaze.¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- Because of immediate post-traumatic swelling, enophthalmos is usually not appreciated clinically until swelling has decreased, unless the orbital blow-out fracture is quite large. Then enophthalmos and dystopia may be immediately appreciated.
- With blow-out fractures, extraocular movements are usually decreased due to the trauma and swelling, but there is usually some degree of movement.
- With entrapment, there is no voluntary extraocular movement due to pain. Attempted upward gaze will result in intense pain, and nausea; bradycardia can also occur.

IMAGING

- CT scan is the modality of choice. All three views are essential.
 - Axial views elucidate whether there is medial wall involvement, and the size.
 - Coronal views elucidate the width of floor fracture, medial wall, inferior rectus muscle involvement, and inferior orbital nerve involvement.
 - Sagittal views elucidate the length of the floor fracture and inferior rectus muscle involvement and helps delineate the depth of the dissection before encountering the posterior shelf.

DIFFERENTIAL DIAGNOSIS

- Need to diagnose other concomitant facial fractures. Most commonly involved are
 - Medial wall
 - Zygomatic maxillary complex
 - Le Fort 2
 - Le Fort 3

NONOPERATIVE MANAGEMENT

- Conservative treatment runs a higher risk of enophthalmos depending on the size of fracture. Amblyopia in pediatric population is generally self-limiting due to the adaptable plasticity of the brain.

SURGICAL MANAGEMENT

Preoperative Planning

- Performing CT scan of axial, coronal, and sagittal planes will help clarify anatomy such as orbital content or inferior rectus entrapment (**FIG 2**).
- Forced duction test under anesthesia if concerned about entrapment. This is difficult to do in an awake patient due to pain despite topical anesthetic drops. I usually defer to CT scan and clinical physical examination of pain and nausea with or without bradycardia upon upward gaze.

Types of Implants

- Synthetic
 - Polyethylene
 - Pros: No donor site and easily cut to size
 - Cons: Does not “grow” with the child, extrusion if not secured adequately, can become infected, and does not have rigidity for adequate support required in extensive orbital floor fracture
 - Titanium
 - Pros: Easily obtainable, retains shape, and easily cut to size, excellent rigidity required for extensive orbital fractures
 - Cons: Does not grow with child, extrusion if not secured adequately, concerns of soft tissue tethering into the openings of the implant^{1,2}

FIG 1 • A. Pediatric skull demonstrating the size of the orbit and forehead compared to the rest of the body. Orbital bones are labeled demonstrating the complexity of the orbital cone. **B.** Pediatric skull demonstrating the size of the superior fissure and the optic foramen in relation to the rest of the orbital cone. Note the size of the superior fissure in proportion to the rest of the orbital cone, as well as its location superomedially. This needs to be taken into account when dissecting on the floor. **C.** Pediatric eye demonstrating the soft tissue anatomy relevant for orbital fracture surgical exposure.

■ Mixed

- Pros: Easily obtainable and has both rigidity and minimal risk of tethering at

implant/soft tissue interface

- Cons: Does not grow with child; risk of extrusion if not secured adequately

■ Autologous

■ Bone

- Pros: Autologous; can be easily shaped
- Cons: Donor-site morbidity; requires time for harvest

■ Cartilage

- Pros: Autologous; can be easily shaped
- Cons: Donor-site morbidity; requires time for harvest

Positioning

- Need to be able to stand at head of bed allowing 270-degree access to the head. Usually turning the bed 90 degrees or 180 degrees provides this access (**FIG 3A**).
- Shoulder roll extending the head to give better visualization of the orbital floor (**FIG 3B,C**).

Approach

- Surgical treatment of orbital fracture can be separated into two different stages. Stage one is the soft tissue exposure and closure, and stage two is the orbital bone repair. Meticulous attention to detail is needed for the soft tissue handling during the exposure and closure because inadequate soft tissue handling can result in severe complications potentially worse than nontreatment. In fact, the actual soft tissue approach can be more morbid than the injury; refined handling of soft tissue is essential for favorable outcomes.³

FIG 2 • A. Preoperative imaging showing orbital floor fracture with entrapped orbital contents. **B.** Postoperative imaging showing orbital contents and floor reduced. No implant was required.

FIG 3 • A. Operating room setup. **B.** Having the patient's neck extended allows an easier angle of viewing into the patient's orbital cone and visualization of the orbital floor. **C.** If the patient's neck is flexed or neutral, the surgeon must lean over to visualize the orbital floor, which is ergonomically more difficult and tiring.

TECHNIQUES

■ Subciliary Approach

- I prefer this approach because it allows a much wider exposure of the rim and floor, as well as provides easier placement of implants onto the floor. Children and young adults have no lid laxity, and this incision avoids retraction on the actual tarsal sling. (Video demonstrates subciliary approach in a case of orbital entrapment.)
- Placement of corneal shield (optional)
- Retention sutures in the lower eyelid. The surgeon can place two sutures, one on each side of the limbus. I like to place the retention suture from the superior eyelid down to the lower eyelid and then back through the upper lid as a horizontal mattress. This protects the cornea and globe, as well as provides retraction during dissection.
- Incise at the lateral corner of the eye of the palpebral crease and plan for incision to be 2 to 3 mm below lash line (**TECH FIG 1A**) extending to the medial lash line to achieve adequate exposure.
- Dissect with tenotomy scissors under the skin in front of the septum but underneath the orbicularis oculi. Using scissors, cut at a bevel to raise a skin and muscle flap (**TECH FIG 1B**).
- Using traction of the lower eyelid retention stitch, spread transversely along the plane to expose the natural plane between the septum and orbicularis oculi (**TECH FIG 1C**). This is continued to the orbital rim. Gentle retraction with a Desmarres retractor while gently pressing down the orbital contents exposes the orbital rim. Avoid making this incision too posteriorly as this will violate the septum; an incision too anteriorly placed will incise the orbicularis oculi muscle.
- Incise the periosteum of the orbital rim with either needle-tip cautery or knife.

TECH FIG 1 • A. Eyelid incisions for approach to the orbital floor. The subciliary incision is preferred as it provides a discreet incision yet allows full exposure of the orbital floor. The lower eyelid incision is much more obvious in patients with youthful skin, such as pediatric and young adults. **B.** Demonstrates the tissue plane between septum and orbicularis oculi allowing an avascular plane of approach to the rim. **C.** Sagittal depiction of the subciliary approach. Note the septum posteriorly and muscle anteriorly. The dissection plane traverses between these two

structures. **D.** Closure of the orbital septum to its anatomic position assists in decreasing ocularis oculi tethering to the orbital rim, thus decreasing risk of ectropion. **E.** Muscle closure of lower eyelid orbicularis oculi to lower eyelid flap orbicularis oculi. **F.** Skin approximated without any gapping. If there is gapping, readvance the lower eyelid flap in order to decrease ectropion.

- Subperiosteal dissection allows improved exposure and avoids the fat of the orbital contents.
- After reconstruction of the orbital floor, handling of the soft tissue is important to prevent ectropion.
- Reapproximation of the periosteum with either 4-0 or 5-0 Vicryl depending on the amount of soft tissue dissected during exposure. An adequate periosteal bite is required to support the soft tissue of the cheek. This is especially important if there is also a ZMC fracture as this area is completely degloved. If the weight of this deep layer is not supported, the risk of ectropion is extremely high.
- Closure of the septum with resorbable suture such as 5-0 Vicryl (**TECH FIG 1D**).
- Reapproximation of the orbicularis oculi with a resorbable suture such as a 5-0 Vicryl. After this layer is closed, the skin should simply be opposing without any gap of the eyelid in comparison to the contralateral side (**TECH FIG 1E,F**). In fact, a little overlap of the lower eyelid over the incision is ideal. If there is gapping between the skin edges after muscle reapproximation, ectropion will most likely occur. Recheck to be certain that the periosteum is reapproximated appropriately by providing adequate support of the overlying soft tissue. The lower lid muscle and skin flap must be advanced adequately superiorly.
- Final skin closure can be completed with either 6-0 monofilament or 6-0 plain gut. I prefer to run a 5-0 fast or 6-0 fast gut. I also place a 6-0 fast tarsorrhaphy at the lateral limbus to assist in keeping the lower eyelid elevated during postoperative swelling. Patients can raise their upper eyelid enough to see. This suture can be removed at day 5 to 7; however, I usually

just let it degrade, which is usually around 5 to 7 days. This prevents patient discomfort.

■ Transconjunctival Approach

- I prefer not to use this approach in children and younger adults as there is no lid laxity. It can be difficult to assess the whole orbital floor, as well as place the implant. Also, oftentimes, “bowstringing” of the lower lid can occur after reconstructing the inferior canthus, which increases the chance of ectropion or entropion.
- Placement of corneal shield: optional
- Place two lower eyelid traction sutures on each side of the limbus right below the lash line.
- Using a sharp pair of tenotomy scissors, make a lateral cut right at the corner of the lateral palpebral fissure. This transects the lateral canthus separating the inferior limb from the superior limb (**TECH FIG 2A**).
- Reorient the scissors 90 degrees so that they are following the curve of the face, and then incise only the inferior limb of the lateral canthus.
- This should release the canthus to pull the lower eyelid out, thus exposing the inferior fornix. The cascade of vessels behind the tarsus and the transition to only the conjunctiva can be visualized. Make an incision with needle-tip cautery underneath this cascade of vessels. This should be a full-thickness conjunctival incision (**TECH FIG 2B**).
- This allows placement of another traction suture as a horizontal mattress from the upper eyelid skin down to the conjunctival flap, back through the flap to the eyelid, and then a loose knot. This provides tension on the conjunctival flap for easier dissection and keeps the corneal shield secure.
- Dissection plane is the same as before, which is between the orbicularis oculi muscle and the septum. Entering the septum allows fat to herniate out and can make retraction more difficult but does not affect overall exploration and floor reconstruction.
- After floor reconstruction (see below for this procedure), closure consists of 4 steps:
 - Reapproximation of SMAS layer to the periosteum of the orbital rim
 - Reapproximation of the orbicularis oculi
 - The conjunctiva does not necessarily need to be closed. Run a 6-0 fast gut

with wide spacing between bites.

- It is essential to reapproximate the inferior canthal tendon to Whitnall tubercle. One can either take a bite through the periosteum or, if there is no periosteum there, can drill a hole in the bone. The key is to make sure to “redrape” the lid against the globe; otherwise, there will be inadequate opposition of the lower lid against the globe.

TECH FIG 2 • A. Transconjunctival approach to the rim. It can be difficult to get full exposure of a fracture unless the inferior canthal tendon is released, and even then, the exposure is limited without forceful retraction of the lower lid. Although there is more elasticity in a youthful/pediatric lower lid, it is also much tighter requiring more extensive retraction, increasing risk of entropion. **B.** Sagittal depiction of the transconjunctival approach.

■ Lower Eyelid Incision

- This is not an ideal approach for the pediatric population or the young adult, unless there is already a laceration (see **TECH FIG 1A**). In the older adult population, the scar is quite acceptable. If one does use this approach, the patient must be aware that there may be a lid edema superior to this incision for a prolonged time postoperatively.

■ Orbital Floor Dissection

- Subperiosteal dissection posteriorly provides a cleaner dissection plane to expose the fracture and herniated orbital contents (**TECH FIG 3**).⁴
- In larger fractures, it is common to encounter the inferior orbital nerve and this must be separated inferiorly. Removal of comminuted bone fragments will help delineate path of the nerve.
- Sweep laterally and medially to help find the posterior shelf. Using either a malleable or orbital content retractor, retract the orbital contents superiorly allowing the edge of the retractor to rest on the posterior shelf. During this maneuver, let the anesthesiologist know there may be vagal stimulation causing bradycardia. This should provide a clear view of the orbital floor defect to help shape the implant.
- CN II and the superior fissure are located superomedially. Be cautious when dissecting toward the fissure. Having an exact idea of the length of your dissection tool is mandatory; the distance from the rim to the apex of the orbital cone ranges will vary according to the patient's age and can be premeasured in the sagittal window preoperative CT scan.
- Shape the orbital plate, and while gently retracting superiorly, place the plate into position.
- When looking down at the surgical site, the surgeon must be able to see the plate. If the plate cannot be visualized, then the placement is not appropriate and the plate is in the maxillary sinus.

TECH FIG 3 • Amount of exposure capable with a subciliary incision. Orbital floor is easily visualized, including the entrapped orbital contents in this particular case.

- Secure the plate to prevent any form of movement because movement can cause migration and extrusion. One can simply secure the plate with a 4-mm screw in the orbital floor.
- If there is a trap door injury, simply reducing the trapped orbital contents is enough to reduce the orbital floor anatomically. The very elastic nature of the pediatric orbital floor bone causing the trapdoor mechanism is also what allows the bone to reduce, thus obviating the need for an implant. Using a small nerve hook can help reduce the orbital floor into its anatomic location, but one must be careful not to completely fracture the floor. This will turn a greenstick fracture into a complete orbital floor defect requiring reconstruction.

PEARLS AND PITFALLS

Preoperative preparation	■ Judicious infiltration of vasoconstrictive local anesthetic.
Adequate exposure	■ Optimal positioning can improve the ease and efficiency of the procedure. Extension of the head allows better visualization of the orbital floor. ■ Although technically either transconjunctival or subciliary incisions can give adequate exposure, subciliary incision can be more easily extended medially for full exposure of floor and medial wall.
Implant placement	■ Need to have adequate exposure and visualize or palpate the posterior shelf ■ Visualize the implant when looking straight down into the orbit (see FIG 3C)
Soft tissue	■ Resuspension and “no tension” closure will help prevent ectropion and entropion.
Postoperative care	■ Obtain postoperative imaging (either CT scan or skull films). ■ Steroid ophthalmic drops to assist in keeping lower eyelid elevated during postoperative period where swelling can cause “bowstringing” of the lower eyelid

POSTOPERATIVE CARE

- Repeat x-ray; lateral films are adequate to demonstrate appropriate placement. If there are other facial fractures, repeat CT scan. In pediatric patients, avoid unnecessary radiation.
- Temporary tarsorrhaphy
- Steroid ophthalmic ointment or drops
- Head of bed elevated
- Visual checks
- Sinus precautions

COMPLICATIONS

- Diplopia
- Enophthalmos
- Ectropion
- Entropion
- Reconstruction malposition
- Palpebral fissure discrepancy

75 Surgical Correction of Pediatric Midface Fractures

CHAPTER

Eric Lowry Cole and Shelby R. Lies

DEFINITION

- Le Fort fracture
 - Le Fort I dentoalveolar separation including pterygoid plates
 - Le Fort II bilateral pyramidal fracture including pterygoid plates
 - Le Fort III craniofacial separation involving the frontonasal articulation, traversing the orbital walls with disjunction of pterygoid plates and zygomatic arch (**FIG 1**)
- Nasal bone fracture
- Naso-orbitoethmoid fracture
- Zygomaticomaxillary complex fracture
- Frontal bone fracture

ANATOMY

- The zygoma articulates with the frontal bone, maxilla, temporal bone, and sphenoid. All fractures of the zygoma affect the orbital floor or lateral orbital wall.
 - The zygomaticosphenoid junction is the key anatomical articulation in the reduction of these fractures (**FIG 2**).
- Naso-orbitoethmoid (NOE) fractures are defined as a comminuted fracture of the nose and orbit involving the medial orbital walls, ethmoid sinus, and bony and cartilaginous structures of the nose.

FIG 1 • Le Fort fracture classifications.

PATHOGENESIS

- Motor vehicle collisions and assault are the most common causes of facial fractures in children.¹
- Consider possible nonaccidental injury if the history does not match the injury or if there are multiple emergency room visits.
- The prominent cranium and mandible in children make isolated midface fractures uncommon, and their presence should prompt a search for associated intracranial and cervical spine injuries.²
- Pure Le Fort fractures are rare and oblique hemi-Le Fort patterns are more common in children.
- Relative underdevelopment of the maxillary sinus allows the zygomaticomaxillary buttress to resist classic Le Fort I level fractures, and instead, force is transferred to dentoalveolar segments causing alveolar and

dental injuries.

- Le Fort II and Le Fort III level injuries often present with NOE fractures combined with zygomaticomaxillary complex and orbital wall fractures.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Blunt trauma causes fractures at articulations.
- Direct impact to the lateral face may cause an isolated depressed zygomatic arch fracture.

FIG 2 • Zygomaticomaxillary complex articulations.

- Significant medial displacement may result in the loss of lateral facial width or trismus through impingement on the coronoid.
- Higher-velocity injuries often cause comminution and deformity in facial width, orbital rim step-offs, flattening of malar prominence, and globe malposition.

- Assess facial symmetry and occlusion; palpate to determine integrity of frontal bones, orbital rims, and malar eminence of zygomatic arch.
- Check stability of the maxilla including dentoalveolar segments by stabilizing the head and attempting to mobilize the dentition. Ecchymosis may be present in the gingivobuccal sulcus.
- Visual acuity and globe integrity must be documented. Examine extraocular movement and pupillary response.
- Enophthalmos. Lateral and/or inferior displacement of the zygoma may increase orbital volume and lead to enophthalmos. Greater than 3 mm change in globe position compared to contralateral eye appears clinically significant. Relation of the corneal surface to the lateral orbital wall can be measured with a Hertel exophthalmometer device.
- Diplopia. Symptoms occur mostly in upward gaze due to hypotropia where the focus is on the eye with a visual axis lower than the contralateral fixating eye, most commonly with injury to the inferior rectus muscle.
- Traumatic optic neuropathy can present with subtle findings of diminished color perception. Consult an ophthalmologist.
- Oculocardiac reflex involves classic triad of bradycardia, nausea, and syncope. If symptoms occur in any phase of treatment, suspect periorbital entrapment, which necessitates release. Pediatric patients are more prone to sustain a trapdoor deformity of the orbital floor, leading to entrapment and persistent nausea (**FIG 3A,B**).
- Cheek numbness as a result of infraorbital nerve injury.
- NOE fracture deformity includes loss of nasal bridge projection, upturned nose, and telescoping nasal length (**FIG 3C,D**).
- The varying degree of loss of canthal attachment creates an increase in intercanthal distance with blunting of the palpebral fissures. A bowstring test can assess for tendon avulsion.
- Intranasal speculum examination for epistaxis and septal hematoma
- Rule out CSF leak with a tilt test for halo sign and/or beta-transferrin analysis.

IMAGING

- Plain occipitomeatal views demonstrate distraction of articulations and zygomatic arch anatomy.
- Computed tomography (CT) max-face is the diagnostic study of choice to evaluate the characteristics of fracture patterns. Considerable information can

be obtained from CT imaging.

- Manson's classification according to degree of displacement/comminution is useful based on CT³:
 - Minimal displacement, no comminution
 - Moderate displacement, mild comminution
 - Severe displacement, major buttresses comminuted in multiple locations
- Three dimensional (3D) reconstruction offers interpretation of complex fractures (**FIG 4**).

FIG 3 • Restriction of the left eye (**A**) correlating with

radiographic evidence of snapback entrapment **(B)**.
C,D. Preoperative photographs of a patient with hemi–Le Fort II and NOE fracture demonstrate loss of nasal bridge projection, upturned nose, and telescoping nasal length.

FIG 4 • A. Coronal CT hemi–Le Fort II NOE fractures.
B. CT 3D Reconstruction hemi–Le Fort III.

DIFFERENTIAL DIAGNOSIS

- Skull fractures from frontal impact are more common in young children, and older teens have a higher probability of facial fractures.²
- Intracranial abnormalities
- Cervical spine injury
- Nasal bone

- Mandible, particularly the subcondylar region
- Frontoethmoid region
- Orbit, most frequently involving the orbital roof in children under 7, as compared to the floor in adults

NONOPERATIVE MANAGEMENT

- In the pediatric patient, rigid skeletal fixation can do more harm than good. Children have significant capability of bony remodeling and dental compensation.
- Fractures should be managed conservatively whenever possible.
 - Nondisplaced and minimally displaced fractures, in the absence of orbital dysmorphism or malocclusion, may be treated with nonoperative care.
 - Close follow-up and a soft diet for 4 weeks are recommended.
- Bone fragment displacement can be caused by muscles of mastication; therefore, parents should be advised to provide appropriately “mushy” meals that can be squeezed between the fingers and instruct children to avoid force while eating.

SURGICAL MANAGEMENT

- Many of the same principles in the treatment of adult midface fractures apply to children.
 - Notable exceptions include the avoidance of implants in tooth-bearing areas to prevent damage to tooth buds and the use of resorbable plates.
- Resorbable plating systems composed of polylactic and polyglycolic acids are readily available and preferred when possible.
 - The plates are usually resorbed within a year and are of adequate strength for fixation of thin bones.⁴
- The goals of reconstruction include obtaining pretraumatic occlusion along with re-establishing the buttresses (medial nasomaxillary and lateral zygomaticomaxillary) to restore the width and projection of the midface.
- The indications for surgical treatment of fractures include malocclusion, trismus, and significant displacement causing enophthalmos or a noticeable contour deformity.
- Treatment involves open reduction and fixation with miniplates, preferably resorbable.
 - Le Fort I displaced fractures require MMF and ORIF of the medial nasomaxillary and lateral zygomaticomaxillary buttresses.

- Le Fort II fractures are often unilateral (hemi) and can present with NOE fractures. Treatment of displaced fractures requires fixation of the medial and lateral buttresses and the orbital rim. A coronal incision may be necessary to address the nasofrontal region.
 - NOE fractures are particularly difficult to manage in children.
 - Complete avulsion of the medial canthal tendon is the strongest indication for surgery.
 - Avulsion of the canthal tendon is best managed with open transnasal canthoplasty.
 - Cantilever bone graft should also be considered during primary reconstruction.
- Le Fort III fractures are often unilateral with multiple fragments and present with NOE combined with zygomaticomaxillary complex fractures.
 - Synchronous ORIF of each subunit fracture through existing lacerations, a coronal approach, or a glabellar incision.
 - Lower lid incisions are needed to assess and treat orbital rim and floor defects if present.

Preoperative Planning

- CT scans and 3D reconstructions should be carefully reviewed and available for display intraoperatively.
- Pediatric dental and orthodontic evaluation should be considered especially if impressions and models were taken before injury.
 - A palatal splint can be fabricated to treat palatal fractures without open reduction internal fixation.
- Occlusion and fracture site mobility should be examined.
 - The bowstring test and inserting a clamp intranasally with the index finger externally palpating medial canthus can assess for instability.
- Evaluation of occlusal relationship requires nasotracheal intubation in most cases.
 - Depending on patient's condition, a submental intubation or tracheostomy might also be considered.

Positioning

- The child is placed in the upper corner of the operating table with a shoulder roll, donut cushion under the head, and arms tucked.

- Minimize blood loss with slight head-up position, controlled blood pressure, and local infiltration with epinephrine.
- A Mayfield head ring attachment to bed may facilitate exposure with coronal approach.

Approach

- Incision selection is based on the desired exposure of displaced articulations.
- Surgical approaches include using existing lacerations; the maxillary vestibule; the lower and upper eyelid to expose the infraorbital rim and zygomaticofrontal sutures, respectively; the glabellar approach; the coronal approach; and the temporal Gillies approach for zygomatic arch reduction.
- The ethmoidal approach is not recommended due to potential scar contracture.
 - Le Fort I: Maxillary vestibule
 - Le Fort II: Maxillary vestibule, lower eyelid, with or without coronal
 - Le Fort III: Eyelid, coronal, or glabella
 - Comminuted NOE fractures: Coronal approach

TECHNIQUES

■ Le Fort I Open Reduction Internal Fixation

- Nasotracheal intubation is necessary. An oropharyngeal pack protects the upper aerodigestive tract from blood and debris. First, arch bars are secured to dentition. Developing dentition requires adjustment in securing maxillomandibular fixation.⁵
 - If the patient is less than 2 years old, higher-energy injuries can be managed with closed reduction and acrylic splints secured with circum-mandibular or piriform drop wires.
 - If the patient is 2 to 5 years old, arch bars can be secured to the deciduous teeth.
 - If the patient is 6 to 12 years old with mixed dentition, stable teeth vary by age. From 6 to 7 years, the deciduous molars are relatively stable.
 - At 8 to 10 years, the permanent first molars and central incisors appear.
 - By age 10, adequate permanent teeth allow arch bar placement.
- Local anesthetic with epinephrine is injected in the gingivobuccal sulcus for

hemostatic effect.

- Incise perpendicular to the mucosa with needle-tip electrocautery or scalpel in gingivobuccal sulcus with care to leave a myomucosal cuff for closure.
- Proceed with dissection through the periosteum of the maxillary bone. Perform subperiosteal dissection with malt elevator to expose the fracture site. Identify stable bone above and below the medial and lateral buttresses.
- Reduction of the maxilla may be difficult due to telescoping and impaction and may be complicated if healing has commenced because of significant time between injury and treatment. Rowe disimpaction forceps may be needed to obtain adequate repositioning of the maxilla. A Stromeyer hook can also be placed in the piriform aperture and used for manipulation.
- After the fracture has been mobilized, remove the throat pack and secure MMF with wires.
- Ensure the condyles are properly seated, and reduce the maxilla for optimal bone contact. Five-millimeter or smaller gaps may be tolerated⁶; however, for comminuted fractures with a larger bony defect, a bone graft may be required for complete osteosynthesis.
- Resorbable plates may be used to decrease the risk of growth disturbances and injury to tooth buds.⁷ The plate is contoured and secured across the zygomaticomaxillary buttress. An additional plate is fixed to the nasomaxillary buttress (**TECH FIG 1**).
- After internal fixation, MMF is released and occlusion is determined. If an open bite or class III occlusion is present, the condyles may not have been seated appropriately in the glenoid fossa. This requires plate removal and repositioning for proper positioning of the condyles.
- The wound is irrigated. The gingivobuccal incision is closed with a 4-0 Vicryl running suture.

TECH FIG 1 • Vestibular approach plating medial and lateral buttresses.

■ Le Fort II Open Reduction Internal Fixation

- Preoperative markings include an existing subtarsal lower eyelid skin crease for orbital rim exposure.
- After nasotracheal intubation and throat pack placement, arch bars are secured to the dentition.
- The fracture segments are exposed through a maxillary vestibular approach.
 - The fracture fragments are mobilized and disimpacted by forceps or bone hooks.
- After adequate reduction, MMF is secured. Reduction and fixation of Le Fort fractures should occur before addressing the orbital wall.
 - A resorbable L-shaped plate is applied to the zygomaticomaxillary buttress. The foot of the plate should be placed in a manner to avoid damage to the tooth roots with screw placement.
- The orbital rim should then be explored. Subtarsal incision is made with a no. 15 blade scalpel and extended through orbicularis oculi preseptally to the orbital rim with a needle-tip electrocautery.
 - Using a Desmarres for retraction, subperiosteal dissection is performed

using an elevator and a curved malleable retractor to widely expose the orbital floor and the orbital wall.

- A contoured plate is applied to the infraorbital rim and secured (**TECH FIG 2A**).
- If the Le Fort II segment is stable, the MMF wires are removed and occlusion is checked.
- Depending on the fracture pattern, an inverted Y-plate or multiple miniplates are used for securing the nasofrontal fracture (**TECH FIG 2B**).
- If there is a defect of the maxillary sinus wall, it may be bridged by resorbable mesh.
- The periosteum is resuspended near the arcus marginalis.
 - The eyelid incisions are closed with 6-0 fast-absorbing gut suture and surgical glue.
 - The gingivobuccal incision is closed with 4-0 Vicryl running suture.

TECH FIG 2 • A. Subtarsal approach infraorbital rim plate. **B.** Plating of a comminuted NOE fracture.

■ Le Fort III Open Reduction Internal Fixation

- Preoperative markings include an existing subtarsal lower eyelid skin crease for orbital rim exposure.
 - Nasotracheal intubation is required to assess occlusal relationship. If not possible, submental intubation should be considered.
 - The hairline can be clipped if a coronal or bitemporal approach is planned.
- Arch bars are secured to dentition.
- The coronal incision is made with a graduated subperiosteal plane, leaving

the pericranium intact superiorly and incising deep through the periosteum several centimeters above the orbital rims (**TECH FIG 3A**).

- If a pericranial flap is planned for frontal sinus injury, however, begin the incision in a subperiosteal plane to raise the skin and pericranial flaps together.
- When approaching the zygomatic arch, to avoid injury to the temporal branch of the facial nerve, transition to incising the deep temporal fascia several centimeters above the arch and dissect within the intermediate fat pad to complete exposure.
- A reduction hook can be used for manipulating the Le Fort complex and zygoma.
 - The tip of the Stromeier hook can be inserted percutaneously 4 cm below the lateral canthus below the arch for repositioning.
 - A threaded reduction tool such as Carroll-Girard might also prove helpful to align the midface in three dimensions.
- Generally, plate fixation is applied to fractures at the zygomaticofrontal suture, the zygomatic arch, and the nasofrontal junction.
- The zygomaticofrontal fracture site can often be palpated. If not exposed through a coronal incision, a 1-cm incision is made directly over the suture site parallel to the lateral orbital rim for exposure.
 - A low-profile resorbable plate may be used for fixation.
- Nasofrontal plates are secured if needed in the appropriate configuration.
- Plates are then applied to the zygomatic arch to reestablish the sagittal buttress (**TECH FIG 3B**).
- After internal fixation, MMF is released and occlusion checked.
- The incisions are closed in layers.
- **TECH FIG 3C** demonstrates a postoperative CT 3D reconstruction with plates in situ.

TECH FIG 3 • A. Coronal exposure graduated plane. **B.** Coronal approach plating zygomaticofrontal articulation and zygomatic arch. **C.** Hemi–Le Fort III postoperative CT 3D reconstruction with zygomaticofrontal, infraorbital rim, nasomaxillary, zygomaticomaxillary buttress, and zygomatic arch plate fixation as well as posts for MMF.

■ **Zygomaticomaxillary Complex Fracture Open Reduction Internal Fixation**

- Preoperative markings include an existing subtarsal lower eyelid skin crease for orbital rim exposure.
- The course of the superficial temporal artery can be palpated and marked to confine the area of the planned Gillies incision within the temporal hairline.
- Surgical approaches typically include the marked lower eyelid, directly over the zygomaticofrontal suture, the Gillies, and the gingivobuccal sulcus to expose displaced articulations. General endotracheal anesthesia is administered.
- The planned areas of dissection are infiltrated for hemostatic effect.
- The zygomaticofrontal fracture site can often be palpated. A 1-cm incision is made directly over the suture site parallel to the lateral orbital rim for exposure.
- The orbital floor should be explored before and after reduction to ensure the fixation did not alter orbital volume or floor stability.
 - Subtarsal incision is made with a no. 15 blade scalpel and extended through orbicularis oculi preseptally to the orbital rim with Colorado tip Bovie electrocautery.
 - Using a Desmarres for retraction, subperiosteal dissection is performed using a Molt no. 9 elevator and a curved malleable retractor to widely expose the orbital floor and the lateral orbital wall to precisely assess anatomic alignment after reduction.
 - Anatomic reduction is largely based on the lateral orbital wall, specifically the relationship of the zygomatic bone and the greater wing of the sphenoid.
 - The zygomaticosphenoid junction is the most accurate assessment of proper reduction.
- The Gillies incision is made and an elevator inserted deep to the temporal fascia superficial to the temporalis muscle to lever the zygomatic arch and obtain restoration of the malar eminence.
 - A Carroll-Girard screw may also prove beneficial to allow manipulation of fragments as a joystick.
- The gingivobuccal sulcus incision is made and subperiosteal dissection performed to expose the zygomaticomaxillary buttress.
- Each fracture line is inspected to assess the correct position at the exposed articulations.
- While holding reduction with a hook on the zygomatic body and the elevator

under the arch, an L-shaped miniplate is used to fixate the ZMB.

- A small resorbable miniplate is used to fixate the ZF suture.
- The orbital floor is again inspected, and if a defect remains, a resorbable mesh implant is placed. A forced duction test is performed.
- The periosteum is resuspended near the arcus marginalis.
 - The eyelid incisions are closed with 6-0 fast-absorbing gut suture and surgical glue.
 - The Gillies is reapproximated with 4-0 Monocryl deep dermal and gut suture.
 - The gingivobuccal incision is closed with 4-0 Vicryl running suture.

PEARLS AND PITFALLS

Proper reduction

- Rowe disimpaction forceps and/or a Stromeyer hook are useful instruments to obtain adequate repositioning of the maxilla. Le Fort I osteotomy may be required if conventional methods are unsuccessful. Zygomaticosphenoid articulation is key to prevent future deformity with regard to orbit volume and facial symmetry.

Conservative management

- Avoid internal fixation for stable or nondisplaced fractures. Use the least invasive approach for manipulation of displaced fragments to obtain acceptable reduction. Good bone remodeling allows satisfactory long-term results.

Implant choice

- Avoid implants in tooth-bearing areas due to the risk of damaging tooth buds. Resorbable fixation decreases the risk of growth disturbances and injury to developing teeth.

Malocclusion

- Check occlusion for open bite or class III tendency. The condylar heads need to be positioned correctly in their respective glenoid fossae when securing MMF.

POSTOPERATIVE CARE

- Visual acuity and extraocular motions are examined in the postanesthesia care unit upon awakening.
- Wire cutters should always be available postoperatively for emergent MMF release.
- Elevate the head of bed, keep incisions clean and dry for 36 hours, and then resume bathing. Allow surgical glue applied to skin incisions to fall off on its

own.

- Chlorhexidine swish and spit TID for 1 week
- Liquid diet for 48 hours
 - Soft diet at least until adequate healing of maxillary vestibular incision
 - Patients in MMF will remain on high-protein liquid diet until MMF release.
 - The duration of MMF is dependent on fracture complexity and stability of fixation.
- For NOE fractures, soft tissue support stressed with compressive dressings and splinting for careful postoperative molding of epicanthal folds during the healing process.
- Oral antibiotics for 3 to 5 days. Analgesics as needed
- Follow up serial physical examination to assess globe position and symmetry as edema subsides

OUTCOMES

- Fortunately, pediatric facial fractures are rare; however, when faced with the challenge of reconstruction, it is important to consider potential future growth deformities while planning restoration of pretraumatic anatomy.
- Cephalometric follow-up shows clinically significant impairment in growth in horizontal and vertical planes.
 - Mean deficiency in growth for all landmarks was 3.7 mm in the x axis and 2.9 mm in the y axis.⁸
- Employ conservative management when possible because children have great capacity for bony remodeling.
- Contour deformities are usually mild. Aesthetic outcome is also dependent on soft tissue involvement (**FIG 5**).
- Orbital function is generally restored fully with proper repair of floor defects.
- Nonunion and malunion are rare.
- Interference with nasal growth and distortion of the medial canthal areas are observed in pediatric NOE fractures if not managed appropriately.

FIG 5 • Postoperative photographs of the patient in **FIG 3C,D** after repair of hemi–Le Fort II and NOE fractures.

COMPLICATIONS

- Complications associated with specific pediatric facial fracture can be classified as intrinsic, secondary to intervention, or resulting from growth and development.⁹
- Malocclusion, TMJ decreased motion, pain
- Facial asymmetry can be caused by inadequate reduction, or ptosis of the malar fat pad, which can be prevented by periosteal suspension of the soft tissue.
- Diplopia can occur initially in 10% of patients with a ZMC fracture; up to 5% may have permanent diplopia.
 - Diplopia occurs most commonly with injury to the inferior rectus muscle.
 - Follow up with scans, and if no improvement is seen in 4 to 6 months, the patient may need rebalancing of extraocular muscles.
- Enophthalmos is defined as posterior displacement of the globe within the orbit due to changes in the volume of the orbital vault relative to its contents.
 - There is approximately 1 mm of enophthalmos for every cubic centimeter increase in orbital volume. Greater than 3 mm change in globe position compared to contralateral eye appears clinically significant.
 - Approximately 20% of patients with orbital fractures have globe malposition.

It is most commonly associated with incomplete zygomatic reduction.

- Etiology of enophthalmos includes fractured medial wall composed of thin lamina papyracea, fat atrophy, extraocular muscle atrophy, and scar contracture.
- Mild to moderate deformity can be corrected with orbital floor implants.
- Available options to fill appropriate volume include bioresorbable mesh, biocompatible porous polyethylene, and/or titanium implants; bone graft is preferable for the pediatric patient. Convert every 1.5 cc of graft material to get 1 mm of globe position advancement. The corrected eye should look proptotic compared to the contralateral eye on the table.
- Severe enophthalmos requires osteotomies and repositioning of the zygoma.
- Traumatic optic neuropathy can occur in 1% to 2% with ZMC fractures. This condition can present with subtle findings of diminished color perception.
- Consult an ophthalmologist, treat with steroids, and assess for improvement or stabilization of visual deficit *prior* to surgical intervention.
- Bradycardia: The oculocardiac reflex involves classic triad of bradycardia, nausea, and syncope. The reflex is mediated by the ophthalmic division of the trigeminal nerve, which passes through the reticular formation to the vagus visceral motor nuclei. The efferent limb message is carried by the vagus nerve to the heart.
- If symptoms occur in any phase of treatment, suspect periorbital entrapment, which necessitates release.
- Inadequate reduction of the zygomaticomaxillary complex causes loss of midface projection, increased facial width, and enophthalmos, which should be avoided by proper planning and assessment of alignment throughout the operation.
- NOE: Complications of untreated NOE fractures include nasolacrimal duct obstruction, telecanthus, and saddle nose deformity. Repair includes ORIF and cantilever bone graft.
- Nasal and septal deformities may require secondary rhinoplasty after completion of midfacial growth.

76 Management of Pediatric Mandible Fractures

CHAPTER

Nataliya I. Biskup and Brian S. Pan

DEFINITION

- The pediatric facial skeleton is largely protected from fractures due to larger facial fat pads, more malleable bone, and a larger head-to-face ratio compared to that of adults.¹
- Mandible fractures are one of the most common pediatric facial fractures.²
- Proper management of the pediatric mandible fracture is critical to limit disruptions in growth and dental development that can ultimately impact occlusion and function.

ANATOMY

- The mandible is a unique bone composed of vertical and horizontal elements that form a U-shaped construct.
- The growth pattern of the mandible occurs in a superior and posterior direction, resulting in a concomitant downward and forward displacement of the mandibular body and symphysis.³
- From early childhood through adolescence, the inferior alveolar nerve changes in position as the canal migrates cephalically from the lingual inferior border of the mandible to a more superior position.
- The preadolescent mandible has high osteogenic potential due to its rich blood supply from the inferior alveolar artery.
- Following permanent tooth eruption, the medullary center of the mandible becomes more thickened and calcified.

PATHOGENESIS

- The most common cause for facial injuries in children is motor vehicle

collisions.

- Sports-related injuries are the second most common cause of facial fractures.
- These injuries occur more commonly in older children and in adolescence.
- Childhood falls and assault/nonaccidental trauma are the least common causes.
- Assaults occur most commonly in adolescence.
- Males are twice as likely to sustain facial fractures compared with females.⁴
- Condyle fractures are considered the most common type of mandible fractures followed by the symphysis, the body of the mandible, the angle, and lastly the ramus.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Depending upon the age of the child, an accurate history may not be available.
- If patient compliance for an adequate exam is not possible, proceed with imaging and consider an exam under sedation.
- Physical exam findings may include pain on palpation over the fracture site, malocclusion, decreased maximal incisive opening, jaw deviation with opening, loose teeth, and intraoral lacerations or ecchymosis.
- Assess for paresthesia or anesthesia caused by injury of the inferior alveolar and mental nerves.
- Chin abrasions and lacerations, coupled with blood in the external auditory canal, should raise suspicion for a condylar fracture.⁵

IMAGING

- Although a panorex and plain films of the mandible can be obtained, a computed tomographic (CT) scan is the standard for imaging in the setting of facial trauma.
- Cone beam CT (CBCT) scans are another means for accurately diagnosing facial fractures and have the advantage of exposing the child to less radiation.

NONOPERATIVE MANAGEMENT

- Most pediatric mandible fractures are treated conservatively. Minor malocclusions will self-correct by the ability of the pediatric mandible to remodel and with minor orthodontic manipulations at skeletal maturity.
- Children with deciduous and mixed dentition have a capacity for spontaneous occlusal readjustment after injury and treatment, as deciduous teeth are shed and permanent teeth erupt.⁶
- Observation is indicated for:

- Patients with condylar and subcondylar fractures
 - Mild malocclusions may be treated with soft diet and/or maxillomandibular fixation (MMF).
 - Moderate to severe malocclusion may be treated with closed reduction and MMF. Open reduction is rarely indicated, especially in intracapsular fractures. Open reduction risks vascular compromise to the condyle, which is a growth center for the mandible with high remodeling capacity.^{7,8}
- Minimally displaced fractures in the tooth-bearing mandible, namely, parasymphysis, body, angle. These areas are filled with developing tooth follicles, and thus operative intervention should be avoided if possible.
- Start the patient on a mechanical soft diet, rigorous physiotherapy, avoidance of rigorous physical contact, and symptomatic pain control for 4 to 6 weeks. Arrange long-term follow-up to closely monitor mandibular growth.

SURGICAL MANAGEMENT

Position

- Place the patient supine under anesthesia with nasotracheal intubation.
- May consider sedation-only anesthesia, if only closed reduction is to be performed without MMF or with minimal MMF (such as an Ivy loop or lingual splint).

TECHNIQUES

■ Closed Reduction and Maxillomandibular Fixation Options

Reduction

- Reduce fractures manually as appropriate depending on fracture pattern and direction of displacement.
- Verify adequate reduction by assessing occlusion while the patient is in centric relation. The pediatric mandible can tolerate a greater degree of variability in fracture reduction than the adult patient.

IMF Bone Screws

- Obtain preoperative imaging (either CT scan or panorex) to identify

positions of permanent and deciduous dentition.

- Place screws in appropriate locations to avoid injury to dental structures:
 - Verify CT scan (ideally one with 2-mm cuts) to accurately identify location of tooth roots to avoid during screw placement.
- Use self-drilling, self-tapping bone screws, placing at minimum two within the mandible and two within the maxilla (**TECH FIG 1**):
 - Consider placement of a single midline screw in the mandible and one in the maxilla as this can often be adequate for fixation and ideal to avoid tooth roots.
- Secure centric occlusion with 25-gauge wire loops.⁹

Arch Bar Application

- Measure and apply the Erich arch bars of appropriate lengths to the maxilla and mandible to allow for all teeth to be wired.
- Secure the arch bars with prestretched stainless steel 26-gauge wire, passing one end of the wire through the buccal gingiva above the arch bar:
 - The wire is then captured on the lingual side and passed through the lingual gingiva, capturing the wire on the buccal side of the tooth (**TECH FIG 2A**).
 - The ends of the wire are then twisted clockwise until the bar is tightly coapted to the tooth (**TECH FIG 2B**).

TECH FIG 1 • Place at minimum two screws within the mandible and two screws in the maxilla.

- Repeat this process until the majority of the dentition is secured and the arch bars are stable.
- Check the stability of the anchoring teeth with bimanual palpation.
- Cautiously apply wires around deciduous teeth because they are more prone to extraction by wire tightening:
 - Note that primary teeth have short conical roots, wide cervical margins without a well-defined cingulum that makes securing the wire more technically challenging. Ideally, apply arch bars in patients older than 9 to 11 years of age.¹⁰
 - Cautiously, apply wires around erupting secondary teeth; periodontal ligaments are not well attached to the bone, and, therefore, the teeth can be extruded by the wire.
- Use rigid wires or elastics to secure occlusion. Elastics may be better tolerated in children with equivalent outcomes as far as fracture healing and mandibular function (**TECH FIG 2C**).¹¹

Interdental Wiring (Bridle Wire, Ivy Loops)

- Consider Ivy loops in younger patients who are not good candidates for arch bars as interdental wiring is less prone to tooth avulsion.
- Apply Ivy loops or bridle wire using prestretched 26-gauge wire (**TECH FIG 3A**).
- Make an eyelet with the wire and insert between the teeth (step 1).
- Bring the wires around the contralateral side of the teeth (step 2).
- Insert dorsal wire through loop (step 3), and twist the wire until secure (step 4) (**TECH FIG 3B**).
- Apply loops to the mandibular and maxillary dentition.
- Use a 25-gauge wire to secure the eyelets from maxillary dentition to the mandibular dentition.

Circum-mandibular and Drop Piriform Wires

- This form of MMF avoids the risk of damaging tooth buds by penetrating the mandible, avulsing existing teeth with interdental wiring, and

inaccuracies of splint fabrication. Efficacy of this technique may be limited in fractures of the non-tooth-bearing mandible, and these wires can often loosen.

- For a single fracture, place three total wires: two wires mesial (or anterior) to the fracture and one wire distal (or posterior) to the fracture:
 - For double fractures, place four total wires: two wires mesial (anterior) to the fractures and one wire distal (posterior) to each fracture.
- Avoid injuring the mental nerve, which is located at the level of the primary first molar in the deciduous dentition, and the permanent first premolar in permanent dentition:
 - Do not engage the fracture line with the wires.
- To place circum-mandibular wires, pass a 16-gauge intravenous catheter stylet (IVCS) percutaneously from the submandibular region, hugging the lingual cortex, and exit on the lingual side close to the alveolus.
- Pass a 26-gauge wire through the lumen of the IVCS. Clamp wire intraorally to avoid pulling through (**TECH FIG 4A**).

TECH FIG 2 • **A.** Pass one end of the wire through the buccal gingiva above the arch bar. The wire is then captured on the lingual side and passed through the lingual gingiva, capturing the wire on the buccal side of the tooth. **B.** The ends of the wire are then twisted clockwise until the bar is tightly coapted to the tooth. **C.** Place elastics around the arch to securely coapt the dentition.

TECH FIG 3 • **A.** Step 1: Make a loop with the wire and insert between the teeth. Step 2: Bring the wires around the contralateral aspects of the teeth. **B.** Step 3: Insert dorsal wire through loop. Step 4: Twist the wires until secure around the dentition.

A

B

C

TECH FIG 4 • A. Pass a 16-gauge intravenous catheter stylet percutaneously from the submandibular region exiting on the lingual side close to the alveolus. Then pass a 26-gauge wire through the lumen of the IVCS. **B.** Guide the IVCS around the inferior border of the mandible onto the buccal surface, passing the needle and wire through the gingivobuccal sulcus, and recapture the wire. **C.** Use a 1-mm drill to make a hole on each side of the piriform rim, and pass a 26-gauge wire through each side. Twist each wire down.

- Guide the IVCS around the inferior border onto the buccal surface of the mandible, hug the buccal cortex, rotate the IVCS such that the bevel is on the leading side and the wire on the nonleading side. Then, pass the needle and wire through the gingivobuccal sulcus, and recapture the wire, twisting it down between an interdental space (**TECH FIG 4B**)¹²:
 - Twist wires down with enough tension to reduce fractures but not so much tension as to damage the growing bone.
 - These wires may be twisted down over an arch bar.
- Alternatively, an awl may be used to place wires.⁸
- To place drop piriform wires, make a high circumvestibular incision around the piriform aperture, and use a Freer elevator to develop a subperiosteal plane around the rim of the piriform:
 - Release attachments of the anterior nasal spine.
 - Elevate floor of the nose and lateral piriform rim in a subperiosteal plane.
- Use a 1-mm drill to make a hole on each side of the piriform rim, and pass a separate 26-gauge wire through each side (**TECH FIG 4C**):
 - Create a loop of wire by twisting the wire down on an instrument outside the mucosal surface to facilitate future lateral wire removal.
- Use an intermediate wire to engage the two circum-mandibular wires and the piriform drop wire in a triangular arrangement (see **TECH FIG 4C**).¹³

Splint Application

- This form of MMF is especially useful in patients less than 3 years of age

who have few stable dental structures.

- Obtain maxillary and mandibular impressions using alginate impression material.
- Prepare the casts.
- Cut mandibular cast into two pieces at the fracture line and reassemble to articulate with the maxillary dentition in the best occlusion. Affix the two pieces with hot glue:
 - Construction of a well-fitting splint via model surgery is technically challenging and may result in occlusal inaccuracy.
- Construct a lingual splint with an acrylic material. Drill holes in the splint at each interdental space to facilitate the insertion of circumdental wires or apply circum-mandibular wires.

TECH FIG 5 • Mold splint to the reduced mandible and dentition, allow to set, and secure to the mandible with

interdental or circum-mandibular wires.

- Reduce fracture, and insert the splint on the lingual aspect of the mandible:
 - Pass 25-gauge wires from the splint holes to the corresponding interdental spaces and then around each erupted tooth.
 - Alternatively, manufacture the splint in one stage in the operating room:
 - Reduce fracture manually and secure reduction with interdental wiring or monocortical bone wires.
 - Apply catalyst-activated acrylic material to mold splint, allow to set, and then secure to the mandible with interdental or circum-mandibular wires¹⁰ (**TECH FIG 5**).
 - Remove the splint at 2 to 3 weeks if the occlusion is stable.¹⁴
-

■ Open Reduction and Internal Fixation

- Apply Erich arch bars.
- For patients without dentition, use circum-mandibular wiring, or drop piriform aperture suspension wires.
- For patients with deciduous dentition (3–6 years old), tooth roots are strong enough to withstand interdental wiring.
- For patients with mixed dentition (6–12 years old), apply MMF carefully (refer to adult mandibular MMF) as deciduous roots may be undergoing resorption by permanent dentition:
 - Consider obtaining a panorex to verify root status of each tooth. If many unstable and resorbing roots are present, use circum-mandibular wiring, acrylic splints, or drop piriform wires.
- For patients with adult dentition, apply MMF as one would for an adult.
- Employ the least invasive surgical approach to access the fracture and allow stable reduction.¹⁵
- Inject fracture sites and proposed incision sites with 0.25% lidocaine with epinephrine 1:400 000.
- Use needle-point cautery to incise:
 - In gingivobuccal sulcus for parasymphysis or body fractures (**TECH FIG 6A**)
 - Along external oblique ridge for angle and ramus fractures

- Use a Freer elevator to expose fractures.
 - Limit exposure to only what is needed to reduce and fixate the fracture.
- Expose inferior border clearly as this is the safest place to plate and apply screws, especially in patients less than 9 years of age (**TECH FIG 6B**).

TECH FIG 6 • **A.** Incise along the gingivobuccal sulcus over the fracture site (parasymphysis fracture). **B.** Expose the fracture and the inferior border of the mandible. **C.** Place plate along the inferior border of the mandible, and adapt the plate to site passively along the bony surface.

- Curette the fracture site to debride the callus. Do so conservatively to avoid tooth root and tooth bud injury.
- Reduce fracture. Avoid bone reduction clamps as these require deep purchase and can migrate through the bone.

- Place the patient into MMF.
- Apply preferred plating system. May consider resorbable plates, as they have been shown safe and effective in pediatric fractures^{16,17}
 - Consider application of MMF concurrently with resorbable fixation.
 - Resorbable systems require a large plate and larger screws to provide similar stability as a titanium plate, thus increasing the risk of root injury during tapping and plate application.
- May use titanium plates; however, these should be removed in 3 to 6 months after fracture healing has occurred, especially in patients less than 10.
 - When applying titanium plates and screws, place 1.0- to 1.3-mm plates in those under 3 years, 1.3 to 1.5 mm in 4 to 9 years, and 2.0 mm in preadolescents and adolescents.
 - Place the plates along the inferior-most portion of the mandibular border.
 - Adapt the plate to sit passively along the bony surface (**TECH FIG 6C**).¹⁰
- Use monocortical screws almost exclusively.
 - Reserve bicortical screws for patients older than 11 years of age.
 - Apply plates along the inferior-most position of the mandibular border, and direct screws posteromedially, not superiorly.
- If fixation of the superior mandibular border is required, do so with interdental wiring and splinting to avoid tooth root injury.
- Test occlusion by releasing the patient from MMF, and gently lift the mandible by grasping the lower lip:
 - If the patient's occlusion is appropriate, replace MMF with wires or elastics.
- Close incision with resorbable suture.

PEARLS AND PITFALLS

Preoperative

- Rule out cervical spine injury given that the force to produce a fracture of the pediatric mandible is significant.
- Conservative management should be strongly considered in nondisplaced and minimally displaced fractures.

Physical findings

- Malocclusion is the most sensitive finding for diagnosis of a mandible fracture.

	■ If compliance during examination is an issue, repeat exam under sedation or anesthesia.
Technique	■ Avoid injuring teeth, tooth roots, and tooth buds. The patient's dentition will determine the technique for MMF. ■ Pediatric fractures have a higher tolerance for variability in reduction due to restitutional remodeling, but gross malocclusion is unacceptable.
Postoperative	■ Follow these patients long term as the child's growth needs to be monitored until after the pubertal growth spurt. ■ Consider involving an orthodontist for long-term care. Occasionally, functional appliances or corrective jaw surgery may be necessary in the setting of asymmetric growth secondary to condyle fractures. ■ Shorten the period of immobilization and MMF to 2 to 3 wks.

POSTOPERATIVE CARE

- If MMF is utilized, the patient is discharged home with wire cutters and/or scissors to release the elastics holding the dentition in occlusion.
- In the setting of open reduction with internal fixation, consider releasing MMF if the child is cooperative and close supervision is possible.
- If MMF is applied, do not leave on for longer than 2 to 3 weeks as pediatric fractures heal quickly:
 - Temporomandibular joint (TMJ) ankylosis may result from prolonged immobilization.
 - Guiding elastics may be used especially in the setting of a condyle fracture.
- Liquid/pureed diet is indicated postoperatively.
 - A soft diet is initiated at 3 weeks, and a regular diet is resumed at 6 weeks following surgery.
- Chlorhexidine mouthwash is recommended after meals accompanied by gentle tooth brushing.

OUTCOMES/COMPLICATIONS

- Available data suggest that appropriately managed fractures have good long-term functional outcomes.
 - Fractures managed with ORIF with or without MMF were more likely to have adverse outcomes related to dental trauma and TMJ clicking.²
- The impact of mandible fractures on growth is another highly debated topic:

- Multiple studies have suggested that condyle fractures, and those limiting TMJ movement, are prone to causing growth abnormalities.¹⁸
- Other potential complications mirror those encountered in adult patients including dental injuries, hardware infections, and need for subsequent surgery.
- Long term follow-up is indicated especially for patients who have suffered fractures prior to adolescence.

PART 3

Head and Neck Reconstruction

Section I: Anesthesia

1 Local Anesthesia of the Face

CHAPTER

Cerrene N. Giordano and Anthony M. Rossi

DEFINITION

- Local or regional anesthesia involves the injection or application of a medication to a specific area of the body to minimize procedural-related pain.
- Various types of local anesthesia exist including topical, infiltrative, nerve block, and tumescent.
- The number of office-based procedures utilizing local anesthesia continues to rise, particularly in the dermatologic setting.
- In-office procedures performed under local anesthesia have reduced recovery time, decreased cost, and improved safety relative to those performed under general anesthesia or intravenous sedation.

ANATOMY

- Effective local anesthesia for the face, particularly with peripheral nerve blocks, requires a complete understanding of the underlying nervous anatomy.
- The 11 branches of the trigeminal nerve (cranial nerve V) and 2 branches of the cervical plexus (C2, C3) are primarily responsible for the cutaneous sensory innervation of the face and neck (**FIG 1**).
- The trigeminal nerve is divided into three main components—V1 (ophthalmic nerve), V2 (maxillary nerve), and V3 (mandibular nerve) with further smaller divisions.
- V1 is composed of the supraorbital, supratrochlear, infratrochlear, external nasal, and lacrimal nerve branches and is primarily responsible for the sensory innervation of the upper eyelids, glabella, forehead, dorsal nose, and anterior

portion of the scalp.

- V2 is composed of the zygomaticotemporal, zygomaticofacial, and infraorbital branches and supplies innervation to the central face including the lower eyelids, medial cheeks, temples, lateral nasal sidewall and alar rim of the nose, and the upper cutaneous and mucosal lip.
- V3 is composed of the auriculotemporal, buccal, and mental nerves and innervates the lateral and lower halves of the face including the preauricular region, portions of the anterior ear, jawline, chin, and lower lip.
- The supraorbital, infraorbital, and mental nerves exit their respective foramen all located in the midpupillary line.
- Cervical nerves C2 and C3 form the great auricular and lesser occipital nerves that complete the innervation of the lateral and anterior neck, the ear, and the postauricular scalp.

FIG 1 • Trigeminal and cervical plexus nerve distribution.

- The great auricular and lesser occipital nerves emerge from Erb point in the posterior cervical triangle, located approximately at the midpoint of the posterior border of the sternocleidomastoid muscle.
- The greater occipital (C2) and third occipital (C3) nerves supply the posterior scalp and neck.

MECHANISMS OF ACTION

- All local anesthetics share a similar molecular structure composed of a hydrophilic amine and a lipophilic aromatic ring linked together by an intermediate chain that classifies the agent as an ester or amide.
- Both esters and amides cause reversible inhibition of voltage-gated sodium channels within affected nerves, thereby blocking depolarization and inhibiting action potential propagation and ultimately sensation.¹
- Esters, such as tetracaine, procaine, and chlorprocaine, are hydrolyzed by plasma cholinesterases and excreted by the kidneys (Table 1).
- In contrast, amides such as lidocaine, mepivacaine, and bupivacaine are metabolized by microsomal enzymes in the liver.²
- The structural components of the local anesthetic agent determine various parameters for clinical efficacy.
 - The lipid solubility of the aromatic ring influences the diffusion and potency of the product, with more lipid-soluble molecules possessing greater diffusion through the nerve cell membrane resulting in higher potency.
 - Agents that are highly protein-bound have a longer duration of action as they possess a stronger affinity for the sodium-gated ion channels.
 - Speed of onset is determined by the drug dissociation constant (pKa), defined as the pH at which the ionized and nonionized forms of the drug are present in equal amounts.
 - All local anesthetics have a pKa higher than physiologic pH.
 - The closer the pKa is to physiologic pH, the more nonionized form of the medication is present, and the more rapidly the drug penetrates the nerve cell membrane creating its clinical effect.
- Ropivacaine is a newer amide anesthetic that has been shown to have a rapid onset and longer duration of action compared to lidocaine.

NATURAL HISTORY

- The Inca populations were the first to discover the pain-reducing property of the *Erythroxylum coca* plant.²
- In the late 1880s, cocaine was isolated from the plant and used initially in ophthalmologic surgeries.
- Safer alternatives were developed early in the 20th century followed by widespread acceptance within the medical community.
- Lidocaine was the first amide anesthetic to undergo clinical testing in the 1940s, with a faster onset, longer duration, and lower toxicity compared to the

ester formulations available at the time.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Eliciting relevant patient history and performing a physical exam prior to the use of any anesthetic agent are crucial to ensure patient safety and minimize complications.
- Patient history
 - Determine medication allergies and prior exposure to injectable or topical anesthetics.
 - Obtain an up-to-date list of the patient's medications including over-the-counter herbs and agents to avoid potential interactions, particularly with drugs metabolized through the liver.
 - A detailed medical history should be elicited, with particular attention to cardiac, renal, liver, and neurologic diseases.
- Relative contraindications
 - Hypersensitivity to the agent (particularly esters)
 - Application of a topical agent to the skin with impaired barrier function
 - G6PD (glucose-6-phosphate dehydrogenase) enzyme deficiency with the use of EMLA (eutectic mixture of local anesthetics)
 - Significant cardiac or hepatic disease
 - Use of class I antiarrhythmic (tocainide, mexiletine)

Table 1 Anesthetics Used for Local Infiltration

		Duration (min)		Max Recommended Dose (Adults)	
		Without Epinephrine	With Epinephrine	Without Epinephrine	With Epinephrine
Anesthetic	Onset (min)				
Amides					
Articaine	2–4	30–120	60–240	5.0 mg/kg or 350 mg	7.0 mg/kg or 500 mg
Bupivacaine	2–10	120–240	240–480	2.5 mg/kg or 175 mg	3.0 mg/kg or 225 mg
Etidocaine	3–5	200	240–360	4.5 mg/kg or 300 mg	6.5 mg/kg or 400 mg
Lidocaine	<1	30–120	60–400	4.5 mg/kg	7.0 mg/kg

				or 300 mg	or 500 mg
Mepivacaine	3–20	30–120	60–400	6.0 mg/kg or 400 mg	7.0 mg/kg or 550 mg
Prilocaine	5–6	30–120	60–400	7.0 mg/kg or 400 mg	10.0 mg/kg or 600 mg
Esters					
Chloroprocaine	5–6	30–60	N/A	11.0 mg/kg or 800 mg	14.0 mg/kg or 1000 mg
Procaine	5	15–90	30–180	10.0 mg/kg	14.0 mg/kg
Tetracaine	7	120–240	240–480	2.0 mg/kg	2.0 mg/kg

- Use of EMLA in infants under 1 month of age (increased risk of methemoglobinemia)
- Lidocaine is pregnancy category B; however, *lidocaine is excreted in breast milk*; therefore, caution is advised for use in breast-feeding mothers.
- Ocular exposure with EMLA should be avoided due to the presence of sodium hydroxide and the potential for alkaline injury.
- Caution is advised with concomitant use of EMLA and certain methemoglobinemia-inducing medications such as acetaminophen, anesthetics (prilocaine and benzocaine), anticonvulsants, antimalarials, nitrates, sulfonamides, and aniline dyes.
- Physical examination
 - Ensure there is no skin breakdown or signs of infection or inflammatory lesions in areas where the agent will be applied/injected.
- Selection of agent
 - Based on the anticipated procedure, the anesthetic is selected by taking into account the need for topical vs injectable modality, duration of the agent, and location of the procedure.
 - The level of preprocedure patient anxiety should also be assessed and may determine the agent and application type used.

SURGICAL MANAGEMENT

- Facial anesthesia is necessary for a variety of different cutaneous procedures, including skin biopsies, excisions, Mohs micrographic surgery, surgical

reconstruction, and laser and light-based therapies for facial resurfacing, scar revision, or lesion ablation.

- The decision to use an anesthetic and the selection of the agent is dependent partially on the type of procedure performed and the anticipated degree of discomfort.
- Facial nerve blocks are commonly implemented for ablative laser resurfacing of the entire face; however, there are reports of regional cutaneous nerve blocks for larger pigmented or vascular facial lesions as well.
- Regional nerve blocks hold the advantage of minimizing significant tissue distortion, using less total volume of medication, and less patient discomfort, but they are more challenging to administer.
- Tumescent anesthesia is a form of local anesthesia using large volumes of highly dilute anesthetic delivered subcutaneously, first described by Dr. Jeffrey Klein in the 1980s.
 - It can be used alone or with various levels of sedation based on the intended procedure.
 - While there is a wide range of usages for tumescent anesthesia, face and neck uses generally include liposuction, face and neck lifts, dermabrasion, and full-face laser resurfacing.
 - Lower volumes of fluid are infiltrated into the face (100–150 mL per side) when compared with body infiltration, so the concentration of lidocaine may be higher for facial procedures.³

Preoperative Planning

- Obtain an accurate patient weight to calculate the maximum allotted anesthetic dose especially for procedures requiring larger volumes.
- Lidocaine toxicity is dose dependent, and it is critical to remain below the calculated maximum dose.
- It is also important to take into consideration individual patient characteristics as frail, elderly patients or those with underlying liver malfunction may require lower dosages.
- The maximum allotted dose of plain lidocaine for an adult patient is 4.5 mg/kg for whom the addition of epinephrine allows for up to 7 mg/kg⁴ (see Table 1).
- The WiMP formula may also be used for ease of calculating maximum allotted dosages as long as the patient's weight, maximum dosage, and percentage concentration of the agent are known.⁵

- $V \text{ (mL)} = (\text{weight (kg)} \times 0.1 \times \text{maximum dose (mg/kg)}) / \text{percentage concentration}$

Positioning

- Positioning is key to establishing both patient and provider comfort during the procedure.
- Ideally, the patient should be comfortably seated on the exam table with the table leaning back and the feet propped up to minimize a vasovagal reaction.
- The patient's head should be firmly rested against the back of the table to allow for stabilization and minimize sudden movements when the needle is injected.
- It is best when injecting if the patient's eyes are closed so they do not unintentionally pull away if they visualize the needle.
- For the surgeon, the table needs to be at an appropriate height, and the patient needs to be positioned closer to the surgeon's side of the table to avoid excessive bending or reaching.
- The patient's skin is held taut by either the surgeon's nondominant hand or an assistant.
- The surgeon's nondominant hand may be used to stabilize the dominant hand during the injection. Alternatively, the surgeon may rest a few fingers of his or her dominant hand on other parts of the patient's face to stabilize self.
- If an assistant is present, care must be taken to ensure the assistant is far enough from the anticipated injection target to avoid accidental needlestick injury should a sudden movement occur.
- Additionally, the surgeon should be positioned so the needle is facing away from critical anatomic structures such as the globe of the eye to avoid an accidental puncture with unanticipated patient movement.

Approach

- Topical agents
 - The topical anesthetic agents encompass a wide variety of noninvasive, painless products, which are commonly used prior to minimally invasive cosmetic procedures.
 - Topical lidocaine and EMLA (eutectic mixture of local anesthetics) are the two most commonly used topical agents.
 - Lidocaine is available in many formulations including cream, viscous

solution, jelly, ointment, spray, and patches.

- Due to its unique liposomal delivery system to enhance penetration through the stratum corneum, lidocaine 4% cream (LMX-4, Ferndale Laboratories, Ferndale, MI) has the advantage of ease of application without occlusion, more rapid onset compared to EMLA (Astra Pharmaceuticals, Westborough, MA), and availability without a prescription.
- EMLA is a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine hydrochloride. EMLA is applied to intact skin, under occlusion, for a minimum of 1 hour to facilitate absorption.
- The depth of anesthesia is directly proportional to the duration of time the product is left in place, with maximum clinical anesthesia achieved at 2 to 3 hours and clinical effect remaining around 1 to 2 hours post removal of product.⁶
- EMLA is safe for use in pediatric and adult populations, and the dosing is largely based on weight and surface area. The manufacturer recommends a dose of 2 g of EMLA per 10 cm² for 2 hours. The maximum recommended dose is 60 g applied to 400 cm² of normal skin.
- Caution with either product should be exercised with use over large surface areas as prolonged application, large surface area, occlusion, and high concentrations increase the risk for cardiotoxicity and central nervous system toxicity.
- **Injectable agents**
 - Lidocaine and bupivacaine are the two most commonly used injectable agents. Lidocaine has a rapid onset of action, generally less than 1 minute, and lasts on average from 30 to 120 minutes, longer with the addition of epinephrine.⁴
 - Bupivacaine is a slower-acting agent, with a 2- to 10-minute onset; however, it has one of the longest durations of action, lasting 120 to 240 minutes without epinephrine. Because of the longer duration of action, bupivacaine is commonly used in lengthy surgical procedures, but its risk of cardiac and neurologic toxicity remains a concern.
 - Ropivacaine and levobupivacaine are two newer amide anesthetics that have a similar duration of action to bupivacaine with fewer cardiotoxic and central nervous system effects and less pain on injection when compared to lidocaine with epinephrine.
- Infiltrative anesthesia may be combined with other forms of anesthesia such as topical, nerve block, or tumescent for larger or more complex cutaneous

procedures.

- Smaller needle sizes, such as 30 or 32 gauge, should be used, and needles should be replaced frequently to reduce pain on injection.
- Additions to injectable anesthetics such as epinephrine, hyaluronidase, and bicarbonate that can enhance efficacy and/or improve patient comfort will be discussed in another section.

TECHNIQUES

■ Local Infiltration

- Prep the surrounding skin with an antiseptic agent such as alcohol, Betadine, or chlorhexidine immediately prior to injection.
- Stretch the surrounding skin and stabilize the needle with the nondominant hand.
- Quickly pierce the skin with the tip of the needle at a 90-degree angle (**TECH FIG 1**).
 - Injection through an enlarged pore or follicle may minimize patient-perceived pain.
- Aspirate the needle prior to product infiltration to avoid intravascular injection and minimize risk for toxicity.⁴

TECH FIG 1 • Piercing the skin at a 90-degree angle irritates fewer nerve fibers, thereby reducing injection pain.

- Advance the needle tip deep/subdermally first and deposit about 0.5 mL of anesthetic agent.
- Be sure to inject slowly as rapid infiltration and cutaneous distention contribute to increased pain.
- Pause for about 30 seconds, and move the needle more superficially while injecting more volume.⁷

- The needle may be slightly withdrawn and advanced subcutaneously in a fanlike fashion to continue anesthetizing while minimizing the number of painful injection points.
 - Once that region is complete, the needle may be fully withdrawn from the skin and reinserted within 1 cm of the blanched border to continue injecting along the established area.⁷
 - Anterograde injection is recommended to keep the wheal before the needle tip to minimize further pain of the needle.⁷
 - For larger excisions, it is generally recommended to perform a ring block with infiltrative anesthesia around the outside of the ellipse, and supplemental anesthesia may be added centrally only where needed upon testing of the area.
 - Using a longer needle to inject deep into the fascial plane or having additional syringes on hand intraoperatively may be necessary for supplementation based on the depth of the procedure planned.
 - The lowest possible dose to achieve an anesthetic effect should be used to avoid toxicity.
-

■ Facial Nerve Blocks

- There are a number of facial nerve blocks that can be performed, including supraorbital, supratrochlear, infraorbital, infratrochlear, mental, zygomaticofacial, zygomaticotemporal, and external nasal. The most commonly used are supraorbital, supratrochlear, infraorbital, and mental.
- Many authors cite the use of 4% articaine hydrochloride with epinephrine as the preferred agent for facial nerve blocks, but 1% lidocaine with or without epinephrine or mixtures of 1% lidocaine and 0.25% bupivacaine may also be used.
- Generally, 3-mL syringes with small-gauge needles such as 25 or 30 are used to reduce pain. Occasionally, longer needles such as 30 mm may be used to ensure product deposition at the targeted foramen.

Supraorbital and Supratrochlear Nerves

- The supraorbital foramen is located in the mid-pupillary line and is palpated along the orbital rim.
 - The needle is inserted perpendicular to the skin above the foramen and

advanced until contact is achieved with the supraorbital ridge, with care not to enter the foramen and cause damage to the nerve (**TECH FIG 2**).

- The supratrochlear nerve can be blocked with periosteal injection at the medial eyebrow and nasal root junction, about 1 cm medial to the supraorbital foramen.
- About 0.5 to 3 mL of anesthetic solution is deposited periosteally to each location after negative aspiration.

Infraorbital Nerve (Video)

Video p3-c001

- The percutaneous approach for the infraorbital nerve involves palpation of the infraorbital foramen, located in the mid-pupillary line about 1 cm lateral to the ipsilateral nasal ala.⁸ The patient may feel a slight discomfort with palpation, which assists in identification.

TECH FIG 2 • Supraorbital nerve block.

- The injection is placed 1 cm inferior to the foramen, and the needle is tangentially directed and slowly advanced upward until the approximate location of the foramen is reached.
- A small wheal (approximately 0.2 mL) of anesthesia can be placed subdermally prior to advancing the needle to minimize pain.
- Alternatively, topical anesthetic agents can be used to reduce injection-related pain.
 - After negative aspiration, a 0.5- to 2.5-mL bolus of anesthetic solution is very slowly deposited just outside of the foramen.
 - It may be helpful for the injector to leave a finger of the nondominant hand pressed over the foramen for ease of location/identification.
- Extreme caution is advised to avoid needlestick injury.
 - The infraorbital nerve has a slower onset of anesthesia, so it is recommended that this nerve is anesthetized first.⁸
- The intraoral approach to the infraorbital nerve (**TECH FIG 3**) involves first

locating the foramen by gentle palpation of the overlying skin as described above.

- The area is then marked and/or the injector's finger is kept in place as a guide.
- A small wheal (approximately 0.2 mL) of anesthesia is placed in the mucobuccal fold over the second premolar.
- The needle is then advanced further upward toward the marked foramen, remaining parallel to the long axis of the second premolar until the foramen is reached.
- After negative aspiration, a 0.5- to 2.5-mL bolus of anesthetic is slowly placed just outside of the foramen.

TECH FIG 3 • Intraoral approach to infraorbital nerve block.

Mental Nerve

- The mental nerve may be reached percutaneously as well, with identification

of the foramen about midway between the upper and lower edges of the mandible in a direct line with the second bicuspid.

- A small wheal of anesthesia can be injected subdermally and then the needle tip advanced until bone is reached.
- A 0.5- to 2.5-mL bolus of anesthesia is injected just outside of the foramen after careful negative aspiration to avoid intravascular injection.
- The intraoral approach for a mental nerve block is more commonly used (**TECH FIG 4**).
 - Identify landmarks for the mental foramen, which is caudad to the second premolar about midway between the tooth and the inferior mandibular border.
 - While retracting the lower lip, the needle is inserted at the gingival-buccal border at the base of the first bicuspid and directed parallel to the bicuspid in the direction of the foramen.
 - After negative aspiration, a 0.5- to 2.5-mL bolus is injected just outside of the foramen.

TECH FIG 4 • Intraoral approach to mental nerve block.

■ **Tumescent Anesthesia**

Dosing

- Because of the wide variability in the volumes used as well as lidocaine and epinephrine concentrations, specific recommendations for tumescent anesthesia are challenging.³
- Lidocaine is the most commonly used anesthetic agent; however, bupivacaine or a combination of the two has also been described.
- The typical compositions for tumescent anesthesia per 1000 mL of normal 0.9% saline or lactated Ringer solution are shown in Table 2.³
 - Some sources recommend higher concentrations in a smaller volume (250 mL) specifically for facial procedures: 600 to 1000 mg lidocaine (0.24%–0.4%), 1 mg epinephrine, and 5 mEq bicarbonate in 250 mL solution.⁹
- The maximum allotted dose is 55 mg/kg of lidocaine in tumescent solution, though some sources claim that lower dosages such as 35 mg/kg should be used in patients taking medications that potentially interfere with lidocaine metabolism.⁹
- The physician should remain on high alert for a minimum of 24 hours after the procedure, as tumescent anesthesia has a delayed peak of activity and therefore the potential for delayed systemic adverse events.
- Tumescent infiltrate is ideally warmed to 37°C to 40°C to avoid hypothermia.⁹

Procedure³

- Tumescent fluid is injected with either an 18-gauge-long spinal needle or a blunt infiltration cannula depending on the size of the case. Either a large syringe or pneumatic pressure device may be used.
- Intradermal or subdermal blebs of 1% lidocaine and 1:100 000 epinephrine are created at the incision sites.
- A no. 11 blade is used to create 2- to 3-mm incisions. Fluid is infiltrated at a low rate (50 to 200 mL/min) and is adjusted for patient comfort. Infiltration is stopped when the infiltrate is about 5 cm beyond the planned procedure site

or when the subcutaneous tissue is firm.

- Wait about 7 to 10 minutes prior to initiating the procedure.
- Supplementary lidocaine with epinephrine may need to be injected intra-/subdermally along incision lines for complete cutaneous anesthesia.

Table 2 Common Tumescence Analgesia Fluid Formula

Medication	Dose Range	Commonly Used Dose (per 1000 mL 0.9% Normal Saline or Lactated Ringer Solution)
Lidocaine	10 mL of 1% to 60 mL of 2%	50 mL of 1% (500 mg)
Epinephrine (1:100 000)	0.5–2 mL of 1:100 000	1 mL of 1:100 000 (1 mg)
Sodium bicarbonate (8.4%)	10–12.5 mL	10 mL of 8.4% (840 mg)

From Gutowski KA. Tumescence analgesia in plastic surgery. *Plast Reconstr Surg*. 2014;134:50S-57S.

■ Additives

- Certain medications can be added to the main anesthetic agent in order to optimize efficacy and minimize patient discomfort during the procedure.
- Epinephrine is often added to local anesthetics for its vasoconstrictive property to minimize systemic absorption, reduce potential for toxicity, increase anesthetic duration at the target nerves, and minimize bleeding at the operative site.
 - 1:100 000 is commonly used in clinical practice, with recent evidence suggesting that a concentration of 1:200 000 is as effective for facial procedures.
 - Epinephrine is pregnancy category C and is secreted in breast milk and, therefore, should be avoided in this group.
- Sodium bicarbonate is added to some anesthetic solutions because lidocaine solutions are often acidic, contributing to the pain upon injection. Bicarbonate increases the pH and reduces the pain associated with product infiltration. A buffered solution is generally prepared by adding 5 mL of 8.4% sodium bicarbonate to a 50-mL bottle of 1% lidocaine with 1:100 000

epinephrine, which is an approximate 10:1 dilution.

- The concentration of epinephrine decreases more rapidly in a buffered solution; therefore, most practices recommend mixing only minutes to hours prior to use and avoid storing pre-prepared buffered solution. However, there was no reduced lidocaine effectiveness after storage for 1 week.
- In addition, the FDA mandates that sodium bicarbonate is a single-use vial making stock preparation less feasible.
- Warming the solution to 98.6°F to 130°F, particularly when combined with buffering, has been shown to reduce injection-related discomfort.
- Hyaluronidase promotes diffusion of the anesthetic through digestion of the extracellular matrix. Analgesic efficacy is improved over a larger surface area with a mixture of lidocaine and hyaluronidase when compared to lidocaine alone; however, no increase in onset or duration was observed. This may be particularly useful in delicate areas such as the eyelid where much lower volumes of anesthesia are needed to minimize tissue distortion.
- The mixture is prepared with 0.5 mL (75 IU) of bovine testicular hyaluronidase added to 0.5 mL of aqueous 0.5% lidocaine hydrochloride solution.
- This addition to local anesthesia is safe and does not appear to retard wound healing.
- Although allergy to hyaluronidase is exceptionally rare, a preliminary skin test for hypersensitivity is generally recommended in nonemergent situations. In addition, it is recommended that patients with known hypersensitivity to hymenoptera stings avoid hyaluronidase due to potential cross-reactivity.

■ Behavioral and Communication Techniques

- Often, the only pain a patient perceives during a procedure surrounds the anesthetizing process and is not related to the actual procedure itself.
- In addition to the many techniques described above, many behavior or communication techniques have also been proposed.
- Distraction or “talkesthesia” is a popular modality that involves talking with the patient about his or her occupation, hobbies, family, etc. to focus their mind elsewhere.
- Physical distraction is another method, such as vibration, slight pinching of

the skin, and tapping alternate body areas in order to activate nearby “touch” nerve fibers and reduce spinal cord transmission of signals produced by “pain” fibers.^{7,10}

- Application of cold or topical anesthesia to the area can reduce the pain of the needlestick.
- Always alerting the patient prior to injection is crucial to minimize sudden movements and improve safety.

PEARLS AND PITFALLS

Assessment	■ Obtain a detailed medical history, medical allergies, and a current list of medications prior to the use of any anesthetic agent. ■ A complete understanding of facial anatomy is essential in performing successful peripheral nerve blocks.
Techniques	■ Proper patient positioning is key to minimize chances of a vasovagal reaction. ■ Surgeon comfort and patient stabilization during injection minimize risk of unintended needlestick injuries. ■ Injection at a 90-degree angle and into a follicular opening or pore can minimize needle discomfort. ■ Patient distraction is an essential tool to reduce pain perception.
Additives	■ Epinephrine 1:200 000 has been shown to be as efficacious as 1:100 000 concentration with lower toxicity risk. ■ Epinephrine causes vasoconstriction to prolong anesthesia duration, minimize systemic absorption, and reduce intraoperative bleeding.
Toxicity	■ Calculating the weight-based maximum allotted dosage of the anesthetic agent prior to a large procedure is crucial to avoiding toxicity. ■ The surgeon must be very familiar with signs and symptoms of early toxicity so appropriate intervention may take place. ■ Stabilizing the patient and initiating basic life support are the first actions needed if toxicity is suspected.

POSTOPERATIVE CARE

- Most of the postoperative care is going to be dependent on the type of procedure that was performed and the anesthetic agent that was used (see Table

1).

- However, it is important to inform patients that there may be some bruising and swelling partially due to the infiltration of the anesthesia, particularly in sensitive regions such as the eye or lips.
- Patients may need to sleep upright for a few nights to allow downward drainage with gravity and minimize further pressure/swelling. They can be reassured that it will improve within a few days.
- If epinephrine is used with the anesthetic solution, there is a chance of bleeding once the epinephrine vasoconstrictive effect wears off. Patients should hold firm continuous pressure for 30 minutes at a time, and pressure dressings immediately postoperatively are crucial in preventing this complication.
- If the area around or within the mouth was anesthetized, patients will need to avoid hot liquids for a few hours until the anesthetic dissipates to avoid unintentional thermal burns.

COMPLICATIONS

- Common side effects for topical anesthetic agents²:
 - Pallor
 - Erythema
 - Edema
 - Pruritus
 - Dermatitis
 - Alterations in temperature sensations
- Common local injection side effects:
 - Pain
 - Erythema
 - Edema
 - Vasovagal reaction
 - Bruising
- Temporary nerve paralysis: If epinephrine is added, the patient may experience a “shaky” or “jittery” feeling or palpitations.
- Toxicity
 - Local anesthetic systemic toxicity (LAST) largely occurs with inadvertent overdose, intravascular injection, and abnormal product metabolism and can be largely avoided with a thorough history and safe injection techniques.
 - Signs and symptoms of lidocaine toxicity are dose dependent and occur as

follows:

- Above 3 g/mL: nonspecific dizziness and drowsiness
- Above 5 µg/mL: perioral paresthesias, tinnitus, muscle fasciculation
- Above 9 µg/mL: fatal, seizures, coma, respiratory and cardiac arrest
- To minimize toxicity, the correct weight-based dosage should be calculated prior to the procedure either using the maximum recommended dosages for lidocaine based on additives (see Table 1) or by using the WiMP formula (discussed in the Preoperative Planning section).
- The maximum lidocaine dose in tumescent anesthesia is 55 mg/kg.
- Using the lowest recommended dosage and continuous communication with the patient is imperative as early recognition of the signs and symptoms of lidocaine toxicity is crucial to initiating care.
- Needle aspiration prior to injection minimizes the risk of inadvertent intravascular injection.
- The following may be done should inadvertent toxicity occur:
 - Administration of the anesthetic should stop immediately, and if topical, it should be removed.
 - Initiate basic life support and contact emergency services if indicated.
 - Vital signs should be established, and the patient should be closely monitored with regular assessment of airway, breathing, and circulation for at least the following 12 hours as cardiovascular depression can persist or recur even after treatment.
 - Benzodiazepines may be administered should seizures occur; however, propofol must be avoided.²
 - An intravenous lipid emulsion has been used with success in treating LAST. The mechanism remains largely unknown; however, the emulsion preferentially partitions the lipophilic anesthetic from the cardiac tissue, thereby improving cardiac conduction.
- Allergy
 - Many patients will report an “allergy” to the anesthetic or the epinephrine with symptoms of palpitations, sweating, light-headedness, or syncope.
 - This is not a true allergy but either a vasovagal reaction to the injection or effects from the epinephrine.
 - True allergies are exceedingly rare (less than 1% of all adverse reactions) but more common with the ester class of anesthetic agents due to the production of para-aminobenzoic acid (PABA) during hydrolysis.²

- Cross-reactivity between ester and amide agents is extremely uncommon, but amides may contain methylparaben as a preservative, which can result in PABA production and cause complications for PABA-sensitive individuals. Therefore, preservative-free formulations are recommended in this population.
- If an allergy is suspected, patch testing (type IV reaction) or prick testing (type I reaction) can be performed.
- Allergic contact dermatitis is an increasing concern with topical anesthetic agents.
- For patients with true anesthetic allergies, alternatives such as 1% diphenhydramine or bacteriostatic saline (0.9% benzyl alcohol in normal saline) may be used for injection.⁴

Section II: Facial Lacerations

2 Management of Facial Lacerations

CHAPTER

John G. Fernandez

DEFINITION

- Facial lacerations are a common emergency room encounter for a plastic and reconstructive surgeon.
- Nearly 7 million patients require treatment for traumatic lacerations per year in the United States.¹
- Approximately 1.5 to 2 million patients present to the ER with facial lacerations.
- According to a study by Singer et al., nearly 28% of all patients visiting the ER with lacerations had facial lacerations.²
- Most complex injuries require layered closure to decrease tension and improve overall results, although single-layered closure is sufficient in small linear wounds. In select patients, topical skin adhesives are gaining acceptance.¹
- Complex wounds involving the eyelids, nose, lips, and ears may require layered closure. Facial lacerations are often associated with more severe injuries to vital structures; therefore, one needs to be suspicious of more severe underlying injuries.
- Facial lacerations may involve tissue loss and may require skin undermining to achieve tension-free closure.
- Composite tissue loss may require more complex reconstruction to restore lining, support, and coverage.

ANATOMY

- There are several vital structures on the face that impact wound closure and/or reconstruction. These include the parotid duct, lacrimal system, white roll of the lips, eyelid margin, facial nerve, and transverse facial artery (**FIG 1**).
- The face has an abundant blood supply and rich network of lymphatics in the dermis and subdermal areas.

PATHOGENESIS

- There are many causes of facial lacerations including penetrating trauma, blunt trauma, and blast injury. Occasionally, multiple mechanisms may be present (eg, penetrating trauma in the setting of a motor vehicle accident).
- The etiology of the facial laceration should be elicited in the history and physical examination; concomitant injury to musculoskeletal (eg, cervical spine injury) or soft tissues should be ruled out.
- Suspicion for other injuries should be high in patients with high-speed blunt trauma and those with penetrating injuries where the entry and exit wounds are not readily identified.

FIG 1 • Vital structures of the face.

- Clean wounds can be repaired expeditiously. However, contaminated wounds or wounds with a significant amount of devitalized tissues may require debridement and delayed closure.

NATURAL HISTORY

- Most routine facial lacerations that are repaired surgically heal rapidly and without difficulty.
- These wounds, perhaps due to the rich vascular supply of the head and neck, rarely become infected or necrotic.

- Superficial wounds that do not warrant closure heal rapidly by secondary intention often with excellent cosmetic results.
- Delayed revision surgery is possible but in many cases not necessary.
- Occasionally, facial lacerations, particularly those in the periorbital area, may result in prolonged swelling. This is usually managed conservatively with scar massage and, less frequently, compression.
- Trapdoor scarring can occur in rounded lacerations leading to contour deformities and a noticeable scar. These scars can usually be successfully revised by undermining and occasionally with Z-plasty or W-plasty.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The preoperative evaluation for patients with facial lacerations includes a detailed assessment of the mechanism of injury, the etiology of the laceration and timing of injury, and the determination if loss of consciousness was associated with the trauma. In addition, physicians should:
 - Document timing of most recent tetanus immunization
 - Elicit history of keloid or hypertrophic scarring
- Patient factors that may lead to wound healing complications such as diabetes, tobacco use, poor nutritional status, steroid therapy, radiation history, and immunosuppression should be documented.
- Concomitant injury to the facial skeleton should be ruled out either by careful history and physical examination or with radiographic imaging as necessary. In addition, injury to other vital structures in the head and neck should be evaluated.
- Significant periorbital lacerations, particularly those that occur as a result of blunt trauma or projectile injury, require funduscopic and visual acuity examination to assess for globe injury. In addition, extraocular muscle movement should be assessed, if entrapment, muscle injury, or nerve damage is suspected.
- The location, size, depth of wound, tissue loss, and level of wound contamination should be assessed.
- Facial nerve function and sensory changes to the skin should be evaluated. Penetrating injury to the cheek may result in laceration of the facial nerve, parotid duct, or both. Cannulation of the parotid duct and irrigation may be needed to identify the area of injury.

IMAGING

- Imaging studies are not routinely necessary for assessment of simple lacerations.
- If there is a suspicion of skeletal injury or injury to underlying vital structures, however, radiologic evaluation is helpful.
- Noncontrast CT scans of the maxillofacial bones with thin slice axial, coronal, and sagittal views are useful for evaluating facial bone fractures.

DIFFERENTIAL DIAGNOSIS

- Partial-thickness wound
- Full-thickness wound
- Complex soft tissue injury including bone involvement
- Underlying vital structure injury

NONOPERATIVE MANAGEMENT

- Healing by secondary intention is an option for superficial lesions or wounds that are contaminated.
 - In some cases, these wounds heal nicely and require no additional intervention.
 - Revision surgery, laser, or dermabrasion, and other techniques may be necessary, however, for depressed or hypertrophic scars.
- Multiple nonsurgical closure techniques such as adhesive tapes, tissue adhesives, etc. have been described.
 - These options are a useful and cost-effective strategy for simple lacerations that are easily closed without tension, particularly in children for whom anesthesia and suture removal may be traumatic.

SURGICAL MANAGEMENT

- The main indications for surgical repair of facial lacerations are
 - Full-thickness wounds (particularly those that may benefit from a multilayer closure)
 - Complex wounds that include trauma to underlying skeletal structures necessitating operative repair
 - Lacerations that injure the facial nerve or parotid duct
 - Wounds that require debridement of devitalized tissues and/or washout of contaminated wounds
- Lacerations to the underlying facial musculature may also require operative exploration and repair to prevent functional and aesthetic complications.

Preoperative Planning

- Patients should be counseled about the length of time necessary for complete wound healing, the potential need for revision surgery, and the risk of hypertrophic or keloid scarring.
 - Additional procedures that may be helpful, such as dermabrasion, steroid injections, or laser therapy, may also be useful information for the patient.
- Detailed history and physical exam should be completed and relevant radiographic studies should be reviewed.
- Tetanus immunization should be provided if outdated (greater than 10 years since the last immunization).
- Oral or intravenous antibiotics may be useful for contaminated wounds or in patients with comorbid conditions that increase the risk of infections. Lacerations of the ear or exposed cartilage, particularly if the perichondrium is injured, may also benefit from preoperative antibiotics.
- Facial nerve function should be documented and confirmed.
 - High-powered loupes or microscope may be needed for repair and should be available to the surgeon.
- Injuries that may involve the lacrimal drainage system should be examined with magnification, and a Jones test can be used to assess integrity of the duct.

Positioning

- Simple lacerations can be repaired in the emergency room setting if proper instruments and lighting are available.
 - More complex lacerations or the need for sedation may require management in the operating room or in a more monitored setting.
- The patient is positioned in a comfortable setting on the operating room table.
 - The head of bed is slightly elevated and turned 180 degrees from anesthesia and centered under the lights.
 - Pressure points are inspected and protected.
 - Sequential compression devices are placed bilaterally if necessary.

Approach

- The approach is straightforward for laceration repair:
 - Decide if the wound is amenable to layered closure.
 - All wounds are cleaned, irrigated and hemostasis is assured.
 - Debridement is conservative and only planned for devitalized tissue.

TECHNIQUES

■ Administration of Local Anesthetic

- Inject along the wound edges for small wounds.
- Nerve blocks work best for larger or more complex wounds (**TECH FIG 1**; see also chapter on Local Anesthesia of the Face). These blocks are particularly useful for
 - Mental nerve block
 - Infraorbital nerve block
 - Supraorbital or supratrochlear nerve block

TECH FIG 1 • Regional nerve blocks.

■ Wound Irrigation and Preparation of Wound

- The wound is irrigated with normal saline to remove debris and clean the bed prior to closure.
- The goal is to reduce gross contamination and remove foreign bodies such

as glass, large debris, or dirt.³

- Additional sterilization steps can also be performed with dilute Betadine (10%) after irrigation.
- Devitalized tissues are debrided to establish the true size of the defect.
- Overly aggressive debridement of partially ischemic areas can be staged to allow complete demarcation.
- Given the excellent blood supply of the face, some ischemic areas may overcome the initial insult and survive.

TECH FIG 2 • Suture techniques.

■ Primary Wound Closure, Including Underlying

Structures

- Handle all tissues gently and with care to avoid excess trauma.
 - Minimal pressure of the wound edges leads to decreased crush injury and local edema and faster healing time.
 - Undermining of subcutaneous tissue as needed facilitates tension-free closure.
 - Repair of underlying muscle with absorbable suture such as Vicryl or PDS suture can also take tension off of the wound and improve functional/cosmetic outcomes (**TECH FIG 2**).
 - Care should be taken to avoid distortion if large portions of the muscle have been damaged.
 - For skin approximation, place sutures approximately 1 cm from the skin edge, making an effort to evert skin edges and avoid tension.
 - Space the sutures approximately 3 to 5 mm apart from each other.
 - Use multilayered closure with absorbable sutures for deep layers and dermis and 6-0 fast absorbing or 5-0 or 6-0 monofilament for skin reapproximation.
-

■ Repair of Specific Injuries

Parotid Duct Injuries

- Unrepaired parotid duct injuries may lead to development of a sialocele or salivary fistula.
- Be suspicious if laceration is between the external auditory canal and the commissure of the lip. The duct exits intraorally in the region of the second maxillary bicuspid.
- Diagnose the injury by using a small-gauge catheter or angiocath to cannulate the distal orifice, and inject normal saline for retrograde filling of the duct to identify subsequent injury in the wound.
- If the duct is injured, it should be debrided to clean edges and repaired with microsurgical technique using 8-0 monofilament nylon.

Facial Nerve injuries

- Facial nerve injuries are common with penetrating trauma to the face.
 - Injury of buccal branch frequently occurs with parotid duct injury because this facial nerve branch travels near the parotid duct.
- If a clean, sharp laceration to the facial nerve is identified, prompt primary

repair is indicted. The goal is a tension-free repair.

- If no significant nerve gap exists (less than 1 cm), proceed with minimal nerve mobilization and precise epineurial reapproximation.
 - Either the epineurium or perineurium should be reapproximated with 9-0 or 10-0 monofilament.
- If the nerve has been crushed or otherwise damaged, the nerve ends should be sharply debrided and the nerve gap should be assessed.
- If the injury cannot be repaired without tension, nerve grafts harvested from the ansa cervicalis or the sural nerve can be used to bridge the gap.
- These repairs should be done with high-power loupe or microscope magnification to obtain excellent nerve coaptation.

Lacrimal System or Eyelid Injuries

- If an underlying lacrimal injury is detected, the wound should be copiously irrigated and any foreign bodies should be removed.
 - The eyelid is extremely well vascularized, so do not debride unless completely devitalized.
- Next, a silicone stent is placed to prevent stricture formation, as well as repair of the overlying lid laceration.
- For anterior lamella lacerations, a multilayered, tension-free closure is best.
- The orbicularis is repaired with 7-0 absorbable suture, and the skin is reapproximated with 6-0 fast-absorbing suture in running or interrupted fashion.
- Full-thickness lid margin lacerations are repaired in layers, with a buried deep tarsus suture first, followed by realignment of the lash line.
 - It is important to evert this tissue and avoid knots abutting the cornea.

PEARLS AND PITFALLS

Assessment

- Determine vital structure injuries during preoperative assessment and operative exploration.
- Be suspicious of other injuries depending on location and mechanism of injury.

Wound preparation

- Wound irrigation with normal saline decreases bacterial load and is essential for wound preparation in contaminated wounds.
- Antibiotics are not necessary unless the wound is grossly

	contaminated or a bite wound.
Technique	■ Hold the body of the needle with needle driver, where it is flat. ■ Deep layers, including muscle fascia and dermis, should be closed with taper needle and skin closed with a cutting needle. ■ Make sure suture bites are at the same level of tissue, and evert the skin edges to prevent depression or notching during wound contracture.
Postoperative care	■ Keep wound dry for 48 hours. ■ Keep head of bed elevated to minimize edema. ■ Sutures are usually removed in 5–10 days, and the incisions can be bolstered with paper tape to prevent scar separation.
Scar management	■ Starting 3 weeks after repair of laceration, massage incision line twice daily for 2–5 min. ■ Consider micropore taping or using silicone sheets for hypertrophic scars. ■ Laser, dermabrasion, or local steroid injection may be helpful for some patients.

POSTOPERATIVE CARE

- Apply triple antibiotic ointment for the first 24 hours (ophthalmic if periorbital).
- Oral or parenteral antibiotics are generally not necessary for clean wounds; however, these interventions may be useful in contaminated wounds, open facial fractures, and bite injuries. Multiple studies show prophylactic antibiotics do not protect against infection of nonbite wounds.
- Patients may shower 48 hours after repair when epithelialization over the incision line has occurred.
- The head of the bed can be kept elevated 30 to 40 degrees to decrease edema.
- Ice packs are also helpful in the first 24 hours but should be avoided if there is evidence of ischemia or skin flap formation.
- Sutures are removed on postoperative day 5 to 10.

OUTCOMES

- Proper handling of wound edges along with tension-free closure will lead to a low incidence of keloids and hypertrophic scarring.

COMPLICATIONS

- Poor cosmetic outcome including poor scarring

- Infection
- Wound breakdown
- Changes to the local sensation
- Dehiscence
- Parotid duct stricture
- Lacrimal duct stricture
- Mass movement or nerve-related complications

Section III: Scalp and Calvarium

3 Scalp Reconstruction With Rotation Flaps

CHAPTER

Finny George and Evan Matros

DEFINITION

- The scalp serves as a protective layer for underlying deep structures including the calvarium and brain.
- It plays an equally important aesthetic role in providing hair coverage.
- Rotation or local flaps can be useful in reconstructing defects up to 5 cm and can be utilized first, before ascending the reconstructive ladder.
- Replacing like tissue with like tissue results in superior results both aesthetically and functionally, particularly with regard to the presence or absence of hair.
- Adequate scalp compliance and pliability is necessary to effectively rotate adjacent scalp tissues.
 - Patients with tight scalp tissues or those with radiation- or surgery-induced fibrosis will have less pliability and rotation potential. The use of scalp flaps in these patients, as well as those with locally aggressive pathology, exposed hardware, and potential exposure of underlying tissues, may be limited.

ANATOMY

- The layers of the scalp are the skin, subcutaneous network (contains blood vessels, lymphatics, and nerves), galea aponeurotica, areolar plane, and pericranium.¹
 - The skin of the scalp is the thickest of all the skin on the body.

- Vertical septa connecting the galea to the skin minimize shearing.
- The galea is a fibromuscular central tendinous confluence of the occipitalis and frontalis muscles. It is contiguous with the superficial temporal fascia and the SMAS.
- The loose areolar plane is the layer in which separation of the scalp from the cranium occurs during trauma. This property can be used during reconstructive surgery to obtain soft tissue advancement.
- The parietal scalp has the greatest mobility and can be helpful in local tissue recruitment.
- Vascular supply
 - The principal blood supply is the supraorbital, supratrochlear, superficial temporal, occipital, and posterior auricular vessels.
 - The vascular supply is derived from both the internal and external carotid systems and forms a rich collateral network. For example, an entirely avulsed scalp can be replanted after repair of only one major blood vessel.
- Sensory
 - The trigeminal nerve contributions are as follows:
 - Supraorbital and supratrochlear nerves supply the forehead, anterior hairline, and frontoparietal regions.
 - Zygomaticotemporal and auriculotemporal nerves supply the temporal region.
 - The occipital and greater occipital nerves supply the occipital region. These originate from the cervical spinal nerve and plexus.

PATHOGENESIS

- Defects of the scalp often result from trauma, malignancy, or congenital disease.
- Radiation damage creates two potential reconstructive dilemmas. Radiation can cause chronic wounds. It also limits soft tissue compliance for defect closure.
- Underlying calvarial reconstruction with a cranioplasty introduces a foreign body and hardware, which can be a chronic wound source.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pertinent history must include information on:
 - Circumstances surrounding injury
 - If the pathology is secondary to tumor excision, then margin status, potential

for local or systemic dissemination, should be documented. Ideally, reconstruction should be delayed until negative margins are obtained; however, this is not always possible when vital structures or hardware is exposed.

- Prior treatment or operations that were done, including failed treatments
 - Underlying presence of hardware or implants
- History of radiation or chemotherapy, immunosuppression, or connective tissue disorders.
- History of smoking, alcohol abuse, weight loss, diabetes, or bleeding disorders should be documented.
- Physical examination should gather enough knowledge to prepare an accurate preoperative plan.
 - Look for prior incisions, evidence of poor wound healing, and radiation changes (eg, woody, discolored skin with telangiectasia).
 - Examine the skin laxity.
 - Available remaining blood supply to the scalp especially in the setting of prior surgery
 - Areas of numbness should be documented.
 - Doppler examination may be helpful to document course and integrity of arterial supply.
- Chronic wounds should be biopsied to rule out recurrent, residual, or new malignancy.

IMAGING

- Diagnostic studies are typically not needed for reconstructive surgery planning; however, these may be necessary for oncological analysis.

NONOPERATIVE MANAGEMENT

- In poor surgical candidates, nonoperative or conservative management may be possible so long as there is no direct communication with the brain.
- This option is best reserved for patients in whom the calvarium is intact and has not been previously injured by radiation or surgery.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior operative reports should be reviewed to ensure vascularity to the proposed rotation flap.

- Risks specific to this operation should be discussed with the patient:
 - Partial or complete flap loss
 - Alopecia
 - Dog ears
 - Asymmetry
 - Abnormal hair growth pattern
 - Need for further or revisionary surgery
- Preoperative antibiotics are administered.
- Temporary markings should be placed with good lighting and exposure by taking into consideration skin laxity, previous incisions, and hair growth patterns.
- A Doppler probe may be used to identify vessels supplying the proposed flap.
- The flap should be planned so that the secondary defect can be closed either primarily or with the use of a skin graft.
- Local anesthetic can be used to minimize bleeding; however, real-time assessment of flap vascularity may not be possible in the presence of vasoconstrictors such as epinephrine.

Positioning

- Depending on the location of the defect, the patient may need to be supine, prone, or in decubitus position to properly expose the defect and proposed donor scalp.
- Generally, the entire scalp needs to be prepped into the surgical field.
- The leg should be prepped as well in case a skin graft is needed.
- It is generally not essential to shave the scalp prior to surgery, but this may be helpful in patients with multiple previous incisions.

TECHNIQUES

■ Rotation Advancement Flap

- Using a marking pen, the proposed rotation flap should be drawn utilizing a long, curvilinear incision that incorporates at least one named vessel mentioned earlier (**TECH FIG 1A**).
- The length of the rotation flap should be much larger than the diameter of

the defect (approximately five times as big) so that tension is minimized along the flap closure (**TECH FIG 1B**).

- Incision should be made parallel to hair follicles so they are not disrupted.
- The dependent parts of the incision (if any) should be made first so that bleeding does not obstruct visualization of subsequent steps.
- The incision is carried through the galea into the loose areolar plane.
- The flap is extensively undermined within the loose areolar plane. This is the principal plane of dissection. The pericranium needs to be carefully preserved especially if a skin graft is needed (**TECH FIG 1C**).
- The flap is advanced and rotated to close the defect and reapproximated in layers.
 - Any tension should be placed at the base of the flap, not the tip (**TECH FIG 1D**).
- A limited amount of galeal scoring may help tissues advance further; however, this can disrupt vascularity and should be done with care.
- Skin graft placement at the flap donor site should be considered if there is too much tension (**TECH FIG 1E**).
- Drain placement in the subgaleal plane should be considered.
- The resultant dog ear at the pivot point of the flap can be left alone or excised as a Burow triangle.

TECH FIG 1 • A. This patient experienced breakdown of a prior craniotomy incision (left temporoparietal region) after he received radiation treatment. **B.** The dehisced, chronic wound is debrided and excised. The flap dimensions are generous compared to the relatively small defect because of the noncompliant radiated nature of the tissues. **C.** The scalp flap is elevated superficial to the pericranium. The pericranium is necessary to support the skin graft at the flap donor site. **D.** The scalp flap is rotated and advanced into the defect. **E.** The flap is inset, and the defect is completely covered. The donor site was

unable to be closed primarily, necessitating a skin graft, shown here covered with a Xeroform bolster.

PEARLS AND PITFALLS

Planning

- At least one main blood vessel must be included in the flap.
- Use large flaps with wide bases.²

Technique

- The scalp is not as compliant as other soft tissues on the body; as a result, large flaps are generally necessary for even modest defects.
- The need to skin graft the flap donor area must be considered preoperatively and discussed with the patient as it introduces an area of alopecia.
- Leaving the pericranium intact is essential for skin graft survival.
- Although scoring the galea is often done to increase advancement, it should be done with caution because vessels are immediately superficial to the galea.

Avoid

- V-Y local flaps should not be designed on the scalp. Their blood supply comes from beneath so would be disrupted with wide subgaleal undermining.
- Avoid placing the suture line over a critical area.²

POSTOPERATIVE CARE

- Care must be taken to avoid compression of the blood supply to the chosen flap.
- Drains are removed when drainage is less approximately 30 mL/d.
- Bolsters for skin grafts are removed 4 to 10 days after surgery.
- Sutures are removed after 7 to 10 days. In patients with tight skin or history of radiation, sutures may be left in place for longer periods of time (4–6 weeks).

OUTCOMES

- In a large series of 139 patients, Janis et al. retrospectively reviewed scalp reconstruction for oncologic defects ranging from 0.7 to 35 cm in width and found that 18.8% of patients who underwent local flaps developed complications.³

- Newman et al. demonstrated fewer complications with uncomplicated defects measuring less than 150 cm² were closed using local flaps in combination with skin grafts.⁴

COMPLICATIONS

- The most common complications with rotation flaps are bleeding, hematoma, seroma, infection, alopecia, flap necrosis/flap loss, and chronic wound development.

4 Scalp Reconstruction With Free Flaps

CHAPTER

Finny George and Evan Matros

DEFINITION

- Free tissue transfer using microsurgical techniques is considered the highest rung on the reconstructive ladder and is generally reserved for complex and/or large wounds.
- Free flaps should also be considered in situations in which tissue with robust blood supply is needed to optimize healing such as in patients with prior radiotherapy treatment or underlying cranioplasty.
- Unlike adjacent tissue transfer in the form of a scalp flap, any free flap will introduce non-hair-bearing tissue into the region.

ANATOMY¹

- The principal blood supply to the scalp is through the supraorbital, supratrochlear, superficial temporal, occipital, and posterior auricular vessels.
- The most commonly used recipient vessels for free tissue transfer to the scalp are the superficial temporal vessels.
- Alternatively, the occipital vessels are large in size and have been described.
- If regional vessels are unavailable, a vein graft may be necessary to reach the neck vessels.

PATHOGENESIS

- Defects of the scalp often result from trauma, malignancy, or congenital disease. Occasionally, chronic wounds develop after radiation therapy.
- Full-thickness defects exposing the brain are especially problematic because of the risk of cerebrospinal fluid leak and infection.
- Calvarial reconstruction with devascularized bone flaps or foreign material

also increases the risk of infection and wound healing complications.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pertinent history must include information on
 - Circumstances surrounding injury
 - Prior treatment or operations, including failed treatments and presence of hardware or implants
 - History of radiation or chemotherapy, immunosuppression, or connective tissue disorders
 - History of smoking, alcohol abuse, weight loss, diabetes, or bleeding disorders
- Physical examination should gather enough knowledge to prepare an accurate preoperative plan.
 - Look for prior incisions or evidence of radiation damage to determine patency of recipient vessels (**FIG 1**).
 - Previous coronal incisions may extend into the preauricular area, causing damage to the superficial temporal artery and vein.

IMAGING

- Diagnostic studies are typically not needed.
- In the setting of prior surgery, however, one can evaluate potential recipient vessels with Doppler studies or angiography.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior operative reports should be reviewed.

FIG 1 • This patient had been treated with excision, Medpor cranioplasty, and adjuvant radiation for squamous cell cancer on the scalp. **A.** Hardware exposure necessitated definitive flap reconstruction. **B.** Previous rotation flaps and skin grafts can be seen.

Table 1 Free Flap Graft Sources

Pros	Cons
Anterolateral thigh	
• Thin and pliable in patients with suitable body habitus • Supine position for harvest • Primary donor-site closure possible for smaller defects • Potential for two-team surgery • Chimeric flaps can provide both skin and muscle coverage if necessary. • Vascularized fascia can be harvested with the flap and inset below the native skin flap, providing a “second layer” closure. This is helpful in patients with radiation-damaged scalp skin that may result in delayed healing with a simple skin-to-skin closure.	• Large thigh donor-site defects may require skin grafting. • Unpredictable pedicle length
Latissimus dorsi	
• Broad muscle with large surface area. The flap can be placed beneath the remaining scalp skin in patients with a history of irradiation. This “two-layer” repair decreases the risk of wound complications that may arise from dehiscence of the flap to the native scalp skin that may occur when skin-to-skin closure is obtained with skin flaps. This flap is considered by many as the optimal choice for large scalp defects because of its surface area.³	• Lateral repositioning • Lengthy scar with high incidence of donor-site seroma formation • May require scalp skin grafting, thus limiting potential for hair

• Long, large-caliber pedicle • Can be harvested with serratus anterior muscle for even greater surface area • Can be harvested as a myocutaneous flap to provide durable coverage in the posterior scalp for total scalp reconstruction	reconstruction
Rectus abdominis myocutaneous flaps (vertical or transverse rectus flaps)	
• Large skin paddle • Long, large-caliber pedicle • Potential for two-team surgery	• Donor-site hernia • Can be too thick relative to the scalp, making inseting difficult • Limited potential for “two-layer” closure • Ischemic complications in large flaps that extend across the midline

- Risks specific to this operation should be discussed with the patient:
 - Partial or complete flap loss
 - Alopecia
 - Need for further or revisionary surgery in addition to donor-site morbidity
- The patient must be aware that he or she will require a potentially lengthy operation and hospital stay.
- Patients must be informed that flap compromise requires urgent re-exploration, possibly the use of anticoagulants, transfusions, and the need for vein grafting from different portions of the body.
- Long procedures in the decubitus or prone position are at risk for development of pressure sores even despite proper positioning and padding.
- Preoperative antibiotics are administered.
- Temporary markings should be placed with ideal lighting and exposure to delineate areas of laxity, hair growth patterns, and prior surgical incisions.

- A Doppler probe can be used to identify arterial supply of the remaining scalp flap and recipient vessels.
- In addition, during the planning phase, consider the following:
 - The estimated pedicle length necessary to reach the defect.
 - Backup plans for recipient vessels should be anticipated in case of size discrepancy or other potential issues. This may include the use of vein grafts.
- In choosing a free flap, considerations should include thickness of tissues to be replaced, surface area for coverage, desire for full-thickness skin-to-skin closure (as opposed to a skin graft, which may take an extended period to epithelialize).² A variety of flaps are available (Table 1).

Positioning

- One of the goals should be to limit the number of times the patient needs to be repositioned and redraped once asleep. This should therefore be coordinated with oncologic teams if a combined procedure is planned.
- Anterolateral thigh (ALT) flap
 - The patient is placed in a supine position, and the whole lower extremity—from 5 cm above the hip—is included in the operating field.
 - A skin graft donor site should also be prepped and is generally harvested from the same thigh.
- Latissimus dorsi flap
 - The patient is positioned in the lateral decubitus position with padding placed between the shoulder and the neck on the contralateral side to prevent impingement of the brachial plexus by the clavicle.
 - An axillary roll is also used between the inner arm and the lateral thorax.
 - The ipsilateral arm is included in the operating field to allow for free movement.
- Rectus flap
 - The patient is placed in the supine position so that the area from midchest to midthigh is exposed.
 - The skin island of this flap is oriented vertically or transversely along the axis of the rectus abdominis muscle.
- A horseshoe underneath the scalp or cranial pins may facilitate scalp exposure for easy inseting.

TECHNIQUES

■ Superficial Temporal Artery Preparation

- The location of the artery is confirmed by Doppler, and the incision is marked 5 mm medial to the tragus to a point 2 cm above the helical rim.⁴
- The incision is marked 3 to 5 mm medial to the artery to avoid cutting directly on the vessel with skin incision.
- In most cases, the vein is located lateral to the artery and dives deep into the parotid gland dividing into the deep and superficial branches.⁴
- If the vessels are small, then dissection can be continued proximally, and the superficial portion of the parotid gland is divided for exposure. Consider the operating microscope for this dissection to reliably visualize the facial nerve. At this level, the vein is usually 3 to 4 mm in diameter, and the artery is 1.5 to 3.0 mm.⁴
- Avoid injury to the auriculotemporal nerve, which runs parallel to the vessels in the preauricular area.

■ Specific Donor-Site Dissections

Anterolateral Thigh Flap

- The dominant perforator is predictably found within a 3-cm radius at the midpoint of a line between the anterosuperior iliac spine and the superolateral border of the patella.⁵
- However, it should be recognized that the perforator anatomy is variable and in a small minority of cases even absent.
- Using a marking pen, the proposed flap skin island is drawn.
 - The medial aspect of the flap is planned over the rectus femoris muscle such that the lateral intermuscular septum where the perforator emanates is included in the flap center.
 - The medial incision is made first, full thickness, to the level of the fascial plane.
 - Dissection continues in the subfascial plane to identify the dominant skin perforator(s).

- The rectus femoris and vastus lateralis muscles are separated from each other once the intermuscular septum is incised. The rectus femoris muscle is retracted medially until the descending branch of the lateral circumflex femoral vessel comes into view.
- The perforator can be dissected anterograde or retrograde until it joins the lateral circumflex femoral pedicle. If septocutaneous perforators are not found, myocutaneous perforators that come through the vastus muscle will be present, as is the case in many patients.
- The descending branch of the lateral circumflex femoral vessel is traced proximally to its origin with the profunda femoris system. Femoral nerve branches should be preserved if possible.
- The lateral aspect of the skin island is then incised to complete the dissection with care taken to avoid injury to the perforator.

Latissimus Dorsi Myocutaneous Flap

- A skin island can be harvested with the flap to use as a flap monitor postoperatively or to cover the posterior scalp area to decrease the effects of compression. This skin island can be removed later if necessary.
- The proposed skin island can be oriented obliquely or horizontally as necessary. The incision is carried down to the muscle and skin flaps are elevated to expose the anatomic margins of the latissimus muscle.
- The muscle is elevated from the chest wall by finding the loose areolar plane on its undersurface and dissecting in a posterior-to-anterior direction. This is done by dividing the origin at the vertebral column and separating it from the paraspinous muscle fascia and lumbosacral fascia.
- The anterior edge of the latissimus muscle toward the axilla is reflected by identifying the vascular pedicle on its deep surface. The thoracodorsal pedicle gives off a serratus branch, which can be divided if the serratus muscle is not needed for reconstruction.⁶⁻⁸
- The muscular attachments to the humerus are divided.
- If maximum pedicle length is needed, the thoracodorsal pedicle can be traced high into the axilla to the subscapular system with division of the circumflex scapular branches. This may require an additional incision length to improve exposure.

Vertical or Transverse Rectus Abdominis Myocutaneous Flap

- The incision is marked either vertically or transversely on the rectus muscle.

- The incision is made and carried down to the level of the abdominal fascia. The medial and lateral rows of perforating vessels are identified.
 - The flap can be harvested with muscle or as a perforator flap as dictated by reconstructive needs and donor-site anatomy.
 - Care must be taken at the level of the inscriptions because the pedicle can be superficial in these locations.
 - As the undersurface of the muscle is slowly elevated, care is taken to identify the pedicle and prevent shearing forces.
-

■ Microsurgery for Scalp Flaps

- Routine microsurgical repair is performed on any of the flaps listed.
- Vessel size discrepancy can be accommodated using a variety of approaches, including the use of couplers for the vein, interrupted suture technique, and running sutures.
- The vein can be repaired with an anastomotic coupling device or hand sewn based on the surgeon's preference.
- Flap inseting requires soft tissue or muscle placement well beyond the borders of any hardware or cranioplasty to keep incisions away from these areas (**TECH FIG 1**).
- Double-layer closure with placement of the flap muscle or vascularized fascia below the native skin is helpful to prevent exposure of the calvarium or hardware, particularly in patients who have been previously irradiated.

TECH FIG 1 • A. Insetting a latissimus dorsi (LD) flap. **B.** The flap is inset and anastomosed to the right superficial temporal artery and vein. The muscle of the flap is inset well beyond the skin edges. **C.** The LD flap covers the hardware and mesh. The skin paddle is useful in these defects for both skin coverage and flap monitoring. **D.** The muscle portion of the flap is

covered with skin graft. **E.** The final inset and closure.

PEARLS AND PITFALLS

Technique

- ALT flap: Preserve the vascular branch arising from the descending branch of the lateral femoral circumflex artery to the rectus femoris muscle when possible to prevent potential ischemic complications in this muscle.
- LD flap: A skin flap can be used to facilitate postoperative monitoring or avoid pressure on the skin graft in the posterior portions of the flap.
- Rectus flap: Flaps that extend beyond the midline may have ischemic issues leading to partial flap loss and delayed wound healing. Vertically oriented flaps have better blood supply but can be too narrow or too thick in some patients.
- Insetting the flap muscle or skin island on the temple or cheek will effectively lengthen the flap reach if the pedicle is unpredictably short. This may create cosmetic issues requiring correction in a secondary procedure.
- Using a “two-layer” closure with muscle or vascularized fascia below the native scalp skin can decrease severity of wound separation, particularly in patients who have been previously treated with radiation.
- The STA vessels are useful because of their proximity to most scalp defects; however, they are thin walled and require careful dissection. Dissection can be continued into the superficial lobe of the parotid to increase recipient vessel size.

POSTOPERATIVE CARE

- Patient position must be optimized to prevent flap compromise from compression on the vascular pedicle and allow for proper postoperative monitoring.
- Flap monitoring should follow a protocol and be standardized. Given that most thrombotic events occur in the first 24 to 48 hours, more frequent clinical assessments are required during this time period.
- Postoperative anticoagulation should be discussed with ablative teams as risk

of intracranial bleeding may be a relative contraindication. Although there is no consensus on the need for or type of anticoagulation that should be used, we routinely use postoperative antiplatelet therapy for 5 days if not otherwise contraindicated.

- Once it is safe to do so, patients should be encouraged to ambulate.
- Drains are usually removed when the output is less than 30 cc/d.
- Sutures are removed when adequate healing has occurred depending on the quality of the recipient tissues.

OUTCOMES

- There is a 98% success rate using free tissue transfer for complex scalp defects.^{9,10}
- STA/V is available and suitable for microvascular tissue transfer in oncologic scalp reconstruction in most patients. Halvorson et al. found no statistical difference in outcome between using superficial temporal vessels and neck vessels.⁴
- Debulking of the skin paddle can improve the appearance of the protuberant grafts (**FIG 2**).

FIG 2 • **A,B.** Postoperatively, the skin paddle is protuberant and bulky. **C,D.** Debulking of the skin paddle greatly improves appearance and contour.

COMPLICATIONS

- Complication rates were similar between ALT and LD flaps in a 15-year study by Fischer et al.⁹
- Some of the complications from free flap reconstruction include
 - Vascular thrombosis
 - Donor-site morbidity

- Wound complications and infection, related to defect size, age, and smoking⁹
- Flap loss
- Partial flap loss
- Exposed underlying hardware

5 Scalp Reconstruction With Tissue Expansion

CHAPTER

Finny George and Evan Matros

DEFINITION

- Tissue expansion is the process by which an external force is applied to recruit the viscoelastic properties of the scalp to increase the size of the available healthy tissue.^{1,2}
- Restoration of the scalp to its prealopecia state is the primary goal of tissue expansion of the scalp. It is a crucial tool in the restoration of hair-bearing scalp.³
- By expanding normal, healthy, hair-bearing scalp tissue, defects up to 50% of the total surface area of the scalp can be resurfaced.
- There are three commonly used tissue expander shapes: round, crescent, and rectangular. The tissue expander shape used is not critical.
- For large defects, multiple tissue expanders can be used simultaneously.
- The base diameter of the expander should be approximately 2 to 2.5 times the size of the defect.

ANATOMY

- The layers of the scalp are the skin, subcutaneous network (contains blood vessels, lymphatics, and nerves), galea aponeurotica, areolar plane, and pericranium.⁴
- The galea is a fibromuscular central tendinous confluence of the occipitalis and frontalis muscles.
- The loose areolar plane, deep to the galea, is the layer in which natural plane of separation of the scalp from the cranium occurs.
- The parietal scalp has the greatest mobility and so can be helpful in local tissue recruitment. This quality can be used in tissue expansion.

- During the process of expansion, predictable changes occur histologically^{1,2,5}:
 - The epidermis thickens, dermis thins, muscle thins, quantity of myofibroblasts increases, 30% to 50% of fat is permanently lost, high density of blood vessels grow, and a collagen/fibroblast capsule forms around the expander.
 - This increased angiogenesis that occurs in expanded flaps allows for improved survival and reliability.
- Expanders are placed in the subgaleal plane, superficial to the pericranium.

PATHOGENESIS

- Alopecia of the scalp often results from trauma, burns, radiation, malignancy, or congenital disease (**FIG 1**).
- Irradiated scalp may not expand well or may be associated with higher complication rates.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pertinent history must be gathered from the patient and will include information on:
 - Circumstances surrounding development of scalp alopecia
 - Prior treatment or operations that were done, including failed treatments
 - Prior use of hardware or implants
 - History of radiation or chemotherapy
 - History of smoking, alcohol abuse, weight loss, diabetes, or bleeding disorders
- Physical examination should gather enough knowledge to prepare an accurate preoperative plan.
 - Look for prior incisions.
 - Examine the skin quality and laxity.
 - Note unusual hair growth patterns including cowlicks.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior operative dictations should be reviewed to ensure that vascularity to the proposed area of expansion has not been disrupted or the area has not been irradiated.
- The patient must be aware that he or she will have an abnormal appearance

during the expansion process and that they will have multiple office visits to undergo the expansion.

FIG 1 • This patient had scalp closure with a skin graft following excision of an adnexal tumor. After a disease-free interval, she requested skin graft removal.

- They must be informed that at least two operations will be needed for this type of procedure.
 - Tissue expander placement
 - Tissue expander removal, scalp flap elevation, and closure with removal of alopecia areas
- Risks specific to this operation should be discussed with the patient. They include alopecia along areas of new incisions, exposed tissue expander or inflation port, dog ears, partial or complete scalp flap loss, asymmetry, abnormal hair growth pattern, and the need for further surgery.
- Preoperative antibiotics are administered.
- Temporary markings should be placed on the patient in the preoperative area where there is ideal lighting and exposure, areas of laxity can be assessed, and hair growth patterns can be noted.

Positioning

- Depending on the location of the defect, the patient may need to be supine or prone to properly expose not only the defect but also the proposed donor scalp.
- Generally, the entire scalp needs to be prepped into the surgical field.
- It is not essential to shave the scalp prior to surgery.

Approach

- The tissue expander can be placed immediately adjacent to an area of alopecia or through a remote incision. There are pros and cons to each approach that must be carefully considered.
- A marginal incision can be made approximately 1 cm beyond the area of alopecia or skin graft.
 - A reliable closure needs to be ensured so there is no dehiscence once expansions are initiated.
 - This incision will become the leading edge of the subsequent scalp flap.
- Remote incisions to place the expander away from the area of alopecia will have a more reliable closure; however, the placement of new incisions needs to be along the same line as the future scalp flap. This can be difficult to anticipate.

TECHNIQUES

■ Insertion of Tissue Expander

- Using a marking pen, the proposed incision should be drawn a minimum of 1 cm from the edge of the defect or prior skin graft (**TECH FIG 1A**).
 - This will allow for reliable suture purchase in healthy tissues away from prior skin grafts.
 - Incisions should be made parallel to the defect margin.
- The proposed incision is infiltrated with 1% lidocaine with epinephrine.
- Incision should be made parallel to hair so that follicles are not disrupted.
- The incision is carried through, full-thickness, to the subgaleal plane.
- Adequate undermining is done so as to accommodate the size of the expander with additional laxity to close the incision without tension.
 - An additional 2-cm remote incision is required to place the port of the

expander.

- The expander is irrigated with bacitracin solution and evacuated of all air.
 - The expander is tested with 60 mL of injectable saline to satisfactorily demonstrate competence without leaks. This fluid is then evacuated.
- The expander is placed in the pocket, and the tubing is positioned away from any potential inadvertent puncture (**TECH FIG 1B**).
- The port is secured with two 5-0 Prolene sutures so that it does not flip in the postoperative period, making location and port access difficult.
- A drain is placed in the same pocket as the expander and is brought out through a separate stab incision.
- The scalp incisions are closed in layers (**TECH FIG 1C**).
- Capillary refill is checked throughout the flap making sure that there is no unfavorable tension on the skin or the incision.

TECH FIG 1 • **A.** The uninvolved scalp posterior to the alopecia (bottom of photo) is proposed for expansion and recruitment. The incision should be placed in healthy scalp to facilitate reliable healing of the suture line. **B.** The tissue expander (crescent shaped) and the remote port for filling access. **C.** Placement of the suture line posterior to the injured tissue and skin graft is crucial for healing.

■ Advancement of Flap

- The tissues should ideally be overexpanded at least 20% larger than the size of the defect for tension-free closure after tissue recoil (**TECH FIG 2A**).

- After the expansion process, the patient is brought back to the operating room for removal of the expander and rotation/advancement of the flap.
- As previously mentioned, the incision used to insert the expander was placed 1 cm posterior to the prior skin graft or original defect. During this operation, this intervening bridge of skin is excised, as its blood supply is presumed to be compromised.
- The capsular pocket is entered and the expander is removed (**TECH FIG 2B**).
- The old incision that was made to place the port is also opened and the port is removed.
- A proposed rotation advancement flap is drawn with a marking pen and blood supply to the flap confirmed prior to committing to the incision.
- The incision is made and the scalp elevated in the areolar plane.
 - A Burow triangle may need to be excised in order to equalize the two sides of scalp along the incision.
- Once the scalp is incised, the advancement is checked to ensure that the defect will be adequately covered prior to excision of any skin graft (**TECH FIG 2C**).
 - The periosteum under the skin graft is left intact.
- A drain is placed in the former capsular pocket and brought out through a separate stab incision.
- Hemostasis is achieved, and the incision is closed in a layered fashion (**TECH FIG 2D**).

TECH FIG 2 • A. The scalp has been expanded. **B.** The expander is removed through the previous incision. The expanded scalp is elevated and the capsule is scored if necessary to allow for advancement. **C.** The expanded scalp is draped over the defect to be excised. The skin graft is not excised until it is ensured that the scalp flap is sufficient in dimension. **D.** The defect is excised, and the expanded scalp is advanced over the defect and closed, healthy tissue to healthy tissue. A drain is left in place.

PEARLS AND PITFALLS

Planning	■ At least one main blood vessel must be included in the flap. ■ Prior incisions should be noted.
Technique	■ The tissue expander shape is not as important as its size. It must be significantly larger than the defect to ensure a flap large enough to excise all areas of alopecia. ■ It is more straightforward to place the expander adjacent to areas of alopecia. This approach does not burn any bridges.
Avoid	■ Avoid additional incisions for placement of the expander that could compromise subsequent scalp flap design. ■ Rapid expansion can lead to higher extrusion rates.

POSTOPERATIVE CARE

- Inflation of the expander is started after the incisions have healed and continued until enough soft tissue has been recruited.
 - Expansions are initiated 2 weeks after placement.
 - Inflation is done weekly.
 - The end of the expansion process can be difficult to determine clinically.
 - The amount of tissue available for rotation/advancement is approximately equal to half the circumference of the inflated expander.
- Drains must be left in place until less than 30 mL/d drainage.
- Once the scalp has been sufficiently expanded, approximately 1 month is waited before the second surgery.
- The entire process of expander placement, expansion, and scalp flap takes approximately 3 months.

OUTCOMES

- The reported incidence of complications in scalp reconstruction with tissue expansion is 6% to 25%.⁶
- Governa et al. reported their study of 157 patients with 262 expanders. Complete scalp coverage was obtained in only 62% of the patients.⁷
- Postoperative result is shown in **FIG 2**.

FIG 2 • Six months postoperatively, the patient has normal hair coverage on the scalp.

COMPLICATIONS

- The most common complications with tissue expansion are
 - Pain
 - Scar widening
 - Expander or port exposure
 - Infection
 - Hematoma
- Children under the age of 3 should not have scalp expansion because of unfavorable effects on open cranial sutures.
- Higher complications are associated with expansion in children under age 7 and in patients who have been radiated or burned.
- Rarely, it may be possible to continue expansion if the port or expander itself becomes exposed as long as there are no signs of infection.
- Manders et al. detailed their experience with 41 expanders in 35 burn patients with alopecia. In this review, 25% of patients had major complications requiring alterations in the treatment plan, while 17% had minor problems.⁸

6 Calvarial Reconstruction With Split Rib Grafts

CHAPTER

David A. Staffenberg and Gerald J. Cho

DEFINITION

- The rib cage is made up of paired ribs, sternum, and thoracic vertebrae acting to protect and stabilize the chest cavity.
- Because the rib cage is comprised of 24 ribs and resection of as many as 2 ribs is well tolerated (ie, does not cause chest wall instability), the rib cage is an abundant source of bone graft material.

ANATOMY

- The rib cage or the thoracic cage consists of bone and cartilage.
 - Normally, there are 12 ribs on each side. Each rib articulates with the thoracic vertebral column posteriorly, and the first 10 ribs articulate with the sternum via the costal cartilage.
 - The caudal two ribs are “floating ribs” and lack corresponding costal cartilages (**FIG 1**).
- Rib grafts are technically easier and safer to obtain than split calvarial grafts in children below the age of 8 because the diploe of the calvarium at this age is poorly developed. Moreover, unlike the iliac crest donor site, rib graft harvest is less painful and does not affect growth potential of the pelvis.
- The rib is circumferentially surrounded by cortical bone and has a cancellous core. The rib can be split into two mirror images to increase the surface area.

FIG 1 • The rib cage. Normally, there are 12 ribs on each side. The caudal two ribs are “floating ribs” and lack corresponding costal cartilages.

- Splitting the bone also makes it more malleable to match the cranial contour.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient history and physical exam should document prior history of chest surgery or trauma particularly previous scars and their location, as well as history of prior rib graft harvest.

IMAGING

- Preoperative chest x-rays are rarely necessary prior to harvesting of rib grafts unless there is an unusual finding on physical exam.
- Similarly, postoperative chest x-rays are usually unnecessary even if there is a small violation of the parietal pleura as this rarely leads to a clinically

significant pneumothorax. If there is suspicion of injury to the visceral pleura or lung parenchyma, then a chest x-ray and close clinical observation may be warranted.

SURGICAL MANAGEMENT

Preoperative Planning

- Skin incisions are marked along the relaxed skin tension lines to minimize postoperative scarring.
 - In females, an inframammary fold incision may be used and is located at approximately the level of the fifth rib.
- Incisions are placed lateral to the costochondral junction to avoid harvesting of the costal cartilage, which is not useful for calvarial reconstruction.
- The length of the incision is related to the amount of bone that is necessary. Nevertheless, it is possible to minimize the length of the incision with the use of angled Horsley rib cutters.
- Harvesting of more than two adjacent ribs should be avoided to minimize the risk of flail chest and respiratory compromise.

Positioning

- The patient can be positioned prone or supine as rib harvest is possible from both the anterior and posterior chest.
- The choice for positioning depends largely on the cranioplasty defect to be treated and aiming to avoid repositioning during surgery.

TECHNIQUES

■ Rib Graft Harvest

- The skin is incised and dissection is carried down to the anterior rectus fascia for the anterior approach. The fascia and muscle are split along the underlying rib using careful palpating as a guide (**TECH FIG 1A**).
- The periosteum of the rib is elevated along the length of the bone using Freer or Joseph elevators.
- Care is directed at the inferior border of each rib where the neuromuscular bundle lays under a small overhang. The neuromuscular bundle is carefully

preserved.

- A Doyen elevator (available in pediatric and adult sizes) is used to continue periosteal dissection under the rib and extend the dissection laterally.
- It is most advantageous to first separate the bony rib from the costal cartilage (in the anterior approach) or to use a scalpel to divide the cartilage just medial to the junction while a malleable retractor protects the underlying periosteum and pleura (**TECH FIG 1B**).
- A wet gauze is wrapped around the medial end of the rib being harvested and a Kocher is used to cinch the gauze snugly around the rib. This will prevent unwanted split ends (**TECH FIG 1C**).
- The surgeon's index finger can then gently provide additional length of the graft by sliding it laterally along the rib separating additional periosteal attachments.
- The Horsley rib cutter is carefully placed in position. The surgeon's index finger confirms placement by palpating along the rib and the rib is cut.
 - Some surgeons will ask the anesthesiologist to decrease the tidal volume during the harvest.
- The rib graft is placed in saline, and attention is directed to the harvest site.

TECH FIG 1 • **A.** Surface anatomy. Note prior incision. The regenerated rib can be harvested again, split, and used. **B.** For the anterior approach, the bony rib is first separated from the costal cartilage by using a scalpel to divide the cartilage just medial to the junction, while a malleable retractor protects the underlying periosteum and pleura. **C.** A wet gauze is the wrapped around the medial end of the rib being harvest and a Kocher is used to cinch the gauze snugly around the

rib. This will prevent unwanted split ends.

■ Checking the Harvest Site and Completion

- The harvest site is filled with saline and the anesthesiologist is asked to provide 40 mm Hg pressure to the airway and hold it while the surgeon observes for persistent bubbling.
 - After a suitable period of observation (usually 5–10 seconds), the anesthesiologist resumes normal ventilation.
- Initial but nonsustained bubbling indicates that the parietal pleura has been transgressed, whereas persistent bubbling indicates that both parietal and visceral pleura are injured.
 - In the former scenario, the donor site can be closed without additional attention.
 - In the latter scenario, the surgeon must attempt to identify an obvious rent in the parietal pleura and place a red rubber catheter through it, leaving the wide end above the level of the skin. The donor site is then closed around the catheter. Because the lungs are ventilated with positive pressure, suction does not need to be applied to the red rubber catheter. The catheter is removed after the donor site is closed.
- Closure is performed in layers using resolvable sutures to reapproximate the periosteum. In infants and young patients, the harvested rib may regrow (we have been able to reharvest ribs years later because of this phenomenon).
- Additional anesthetic may be injected into the donor site for postoperative comfort (0.25% Marcaine is frequently used). The surgeon may also make use of commercially available systems to deliver pain medicine to the donor site via a catheter.
- A chest x-ray may be obtained postoperatively to rule out a pneumothorax or hemothorax. When suspicion of a pleural rent is minimal, an x-ray may be avoided.
- The harvested rib is inspected. Any cartilage remnant is removed.
- In children, thin spatula osteotomes are ideal for manually splitting the ribs in a sagittal plane without use of a mallet (**TECH FIG 2**).
 - In infants, a scalpel blade will frequently suffice, whereas in adults, a Frehofer with a mallet will work well.

TECH FIG 2 • **A.** A thin spatula osteotome is used to split the rib. **B.** Splitting rib effectively doubles the surface area.

PEARLS AND PITFALLS

Indications	Split rib grafts are indicated for cranioplasty particularly in children who are less than 8 years old.
Splitting rib graft	Doubles effective surface area, grafts are more malleable to better match contour.
Prior rib harvest	Regenerated rib can be harvested again, split, and used.
Damage to pleura	Rarely clinically significant if limited to parietal pleura.
Amount of rib harvested	It is not recommended to harvest more than two adjacent ribs to minimize the risk of respiratory compromise from a flail chest.

POSTOPERATIVE CARE

- Intercostal nerve blocks and infiltration of surrounding soft tissue with local anesthetics can help reduce postoperative pain at the rib donor site.

- Patients can resume their regular activities/return to school after 2 weeks postop.

OUTCOMES

- Reliable grafts that incorporate well into the adjacent calvarium and accommodate the growing skeleton.^{1,2}
- Split rib grafts contour well and maintain their shape over time.^{3,4}

COMPLICATIONS

- Pneumothorax/hemothorax: If a pneumothorax is present, a small red rubber catheter is placed into the pleural cavity. The overlying muscle is reapproximated and the catheter withdrawn while the anesthesiologist applies positive pressure ventilation.
- Hypertrophic scarring of chest wall incision: Transverse incisions parallel to the resting skin tension lines typically heal more favorably than oblique incisions.
- Chest wall deformity: Rarely, a problem when perichondrium is left intact as there is usually complete regeneration of the donor rib in children. Avoiding violation of the sixth rib margin can prevent outward flaring of the rib as the child grows. Chest wall deformity is more noticeable in extremely thin patients.⁵
- Resorption of graft: Rib grafts have a higher rates of resorption clinically and in animal studies as compared to calvarial bone grafts.⁶

7 Calvarial Reconstruction With Split Calvarial Grafts

CHAPTER

David A. Staffenberg and Gerald J. Cho

DEFINITION

- Split calvarial grafts are cortical bone grafts harvested from the skull.
- These grafts can be either partial-thickness grafts where only the outer cortex is removed or full-thickness grafts that are then split along the diploic space to separate the bicortical graft into two pieces.

ANATOMY

- The calvarium (skull) consists of separate bone plates encasing the brain. Each named bone plate adjoins the adjacent bone plates at the cranial sutures.
 - Paired frontal bones
 - Paired parietal bones
 - Occipital bone (occasionally with an accessory suture or mendosal suture)
- The skull consists of three layers of variable thickness:
 - Outer table (cortical bone)
 - Middle layer (cancellous bone)
 - Inner table (cortical bone)
- These three layers are not present at the cranial sutures.
- The entire calvarium can serve as a donor site for split calvarial grafts. There are two main danger zone, however:
 - The midline, where the sagittal sinus resides subcortically
 - Below the temporal crest, where the bone tends to be thinner, increasing the risk for inadvertent intracranial entry
- Frontal bone can also be used when this is the site of surgery (eg, a frontal craniotomy is performed by the neurosurgeons for tumor access).
 - The craniotomy bone flap can be split, during the neurosurgical portion of the

procedure, if additional bone will be required for repair).

- The thickest bone resides in the parietal and occipital bones.¹ Parietal bone is the most common donor site because it is the thickest.
- Transcortical emissary veins can cause brisk bleeding during the osteotomy. This can usually be controlled with bone wax.
 - Subcortical vessels can cause thinning, and thus, weaken the inner cortex.
- The split calvarial graft may be a superior alternative to other bone graft donor sites.
 - It offers a hidden scar if placed within the hair-bearing scalp.
 - It is frequently a painless donor site, particularly when compared with iliac crest and rib.
- Split calvarium will typically provide cortical bone grafts that have the following advantages over iliac crest and rib:
 - Smooth surface
 - Able to hold screws
 - Able to bear load
 - Warp resistant
- In experienced hands, a large quantity of cortical bone can be harvested.
- Splitting the calvarium is easiest when the diploe is well-developed.

PATIENT HISTORY AND PHYSICAL FINDINGS

- When a donor site is being selected, note the patient's handedness. This is to decrease potential morbidity in case there is inadvertent intracranial entry and damage to the motor cortex.
 - A left-handed patient will have a left side donor site.
 - A right-handed patient will have a right side donor site.
- When there has been previous surgery, the surgeon must take note of:
 - Previous scars, their condition and location
 - Mobility of the scalp: An adherent scalp may indicate loss of the intermediate layers of the scalp and therefore the potential for subsequent wound healing problems.
 - Palpable bony defects or hardware

IMAGING

- Imaging may be useful to determine the characteristics of available sites.
- CT scanning with bone windows is currently the most useful imaging

modality.

- CT is particularly helpful when there are palpable bony defects or hardware present.
- The thickness of the inner and outer tables of the calvarium, as well as the thickness of the diploe, should be noted by the surgeon.
- Imaging is recommended until the surgeon has gained suitable experience.

SURGICAL MANAGEMENT

Preoperative Planning

- If coronal incision is being used, the scalp flaps can be retracted to expose the graft donor site.
- The coronal flap is elevated in a subperiosteal plane if a full outer cortical graft is being harvested down to diploe.
- If a split-thickness (partial thickness outer table) calvarial graft is being harvested, a subgaleal plane is elevated to preserve the periosteum.
- If a coronal incision is not being used, we recommend a sigmoid-shaped incision over the donor site for wide exposure.
- The flaps are elevated in a subperiosteal plane if a full outer cortical graft is being harvested down to diploe.
- If a split-thickness (partial thickness outer table) calvarial graft is being harvested, a subgaleal plane is elevated to preserve periosteum on the intended bone graft.

Positioning

- The patient can be positioned supine or prone.
- The patient's head should be secured and on a firm surface (ie, avoid cushions) to minimize "bouncing" while the osteotomes are driven with a mallet.

Approach

- Ex vivo calvarial split is a useful technique when neurosurgeons are performing a craniotomy for an intracranial procedure and additional cortical bone is required at the completion of the procedure.
- In situ split calvarial is a reasonable option for adult patients and is useful when a craniotomy is not necessary for the surgery at hand. However, there is a greater learning curve than ex vivo technique because inadvertent injury to the inner table may cause dural tears or intracranial injury.

TECHNIQUES

Video p3-c007

■ Ex Vivo Split Calvarial Graft From Craniotomy Bone Flap

- The craniotomy bone flap is placed in saline on a sterile back table.
- We use a table with a drill/saw system secured to a pole because this allows efficient use of the time while the neurosurgery team is working.
- Bone is kept in saline when not being used.
- Instruments are selected based on the age of the patient and the characteristics of the bone to be split.
 - In infants as young as weeks of age, a no. 15 scalpel blade may be an efficient tool for splitting bone through the diploe. A sterile vise applied to the side of the back table is helpful to minimize injuring the surgeon's nondominant hand.
 - In infants from a few months old, a series of spatula osteotomes can be used to gently split the calvarium along the diploe (**TECH FIG 1A,B**).
 - After roughly 6 months of age, a C-1 side-cutting bit on a Midas Rex can be used to create a series of adjacent drill holes while applying copious saline irrigation to prevent thermal necrosis. The C-1 bit can then be used to gently connect each hole (**TECH FIG 1C-E**).
- Several of the popular saw systems have developed flexible saw blades as

thin as 0.3 mm. I prefer using the reciprocating saw for this purpose. Again, use caution to avoid injury to your own hands or those of your assistants.

- While working with the saw, a vise or Kocher clamp can be used to reduce vibration.

TECH FIG 1 • A,B. C-1 side-cutting bur on Midas Rex is used to separate the inner cortex from the outer cortex along the diploic space. Note that the maximal width of bone graft obtained is dictated by the length of the drill. **C.** The drill is used to perforate the inner cortex in a “postage stamp” manner. **D.** The perforations are connected using the drill. **E.** Split calvarial graft is obtained.

■ In Situ Split Calvarial Graft

- The desired donor site is exposed in a subperiosteal plane.
- The desired graft is marked with a sterile pencil, bonny blue, or the like.
- A saline-cooled bur is used to create a trough around the border of the

desired graft; the trough is continued into the diploe. The depth is noted when cancellous bleeding is seen (**TECH FIG 2A**).

- Plan to drive the osteotome toward the floor. Use the bur to bevel the upper margin to make the proper position and angle of the osteotome easier.
 - A selection of slightly curved osteotomes is used along the diploe. Care is exercised to avoid directing the osteotome into the inner table. An assistant secures the patients head to avoid bouncing, while the mallet drives the osteotomes. Rapid light taps are safer and allow frequent correction and adjustment of the osteotome (**TECH FIG 2B**).
- Once the outer table is harvested, the inner table integrity is confirmed. Compromise of the inner table should prompt consideration of a neurosurgical consult intraoperatively.
 - Judicious use of bone wax can control bleeding from the diploe.
- The saline-cooled bur is used to bevel the edges of the donor site to minimize palpability of the step-off.
 - Filling the donor site with an alloplastic “bone paste” may be considered in the hairless, or shaven, patient.
- The scalp is closed in layers. A drain may be used based on the surgeon’s preference. I favor a craniofacial dressing over the use of a drain.

TECH FIG 2 • A. A cutting bur is used to make a trough through the outer cortex and into the diploe. The outer edges are contoured and feathered

peripherally. **B.** The outer cortex is removed using a right-angled oscillating saw, or alternatively, it can be chiseled off using a curved osteotome.

■ Thin Split-Thickness In Situ Calvarial Bone Graft

- Periosteum attached to the intended graft is imperative.
 - An incision is made around the desired dimensions of the graft (scalpel or cautery is acceptable).
 - A wide, sharp osteotome is selected and oriented at about 45 degrees off the outer table with the surgeon's nondominant hand.
 - The surgeon's dominant hand is used to strike the osteotome with a mallet with light but rapid contact. This will "shave" a thin split calvarial bone graft, which is comminuted but held together by the periosteum.
 - The comminution allows the graft to curl, which makes it ideal for repair of an orbital floor defect, ie, acute pure orbital blow-out fracture.
-

PEARLS AND PITFALLS

Patient age	■ Patients at the extremes of age pose a technical challenge and experience is even more critical to minimize morbidity in these patients. Neonates may have an undeveloped diploe, whereas elderly patients lose the diploe, which may present a technical challenge. In situ split-thickness harvesting in these two groups is not recommended.
Intracranial pressure	■ Patients with even subclinical increased intracranial pressure (eg, syndromic craniosynostosis, some nonsyndromic craniosynostosis) may lose the inner table and simply manifest with a monocortical calvarium. Splitting is increasingly more difficult or impossible in areas where the calvarium has thinned.
Know your instruments	■ Know the capability of your instruments (saws, osteotomes, burs, etc.)
Know your own	■ Practice. <i>There is a real learning curve.</i>

POSTOPERATIVE CARE

- Limited exposure and smaller grafts can be managed with simple compressive dressings, which can be removed after a few days.
- Wide exposure for large grafts may require a closed suction drain.

OUTCOMES

- Calvarial bone grafts are considered the standard for autogenous craniofacial reconstructions.^{1,2}
- No controlled human studies currently exist that characterize the volume or rate of absorption. However, numerous clinical studies demonstrate excellent graft stability along the entire craniofacial skeleton. Animal studies have shown calvarial grafts to be superior to rib and iliac crest bone grafts.
- Donor-site complications are rare across all studies.³

COMPLICATIONS

- Dural exposure
 - If small (less than 1 cm²), there is no need for calvarial reconstruction
 - Larger (greater than 1 cm²) defects can be reconstructed with another split calvarial graft or alloplastic mesh.
- Dural tear
 - This complication requires prompt neurosurgical intervention. Injured dura should be adequately exposed and the brain evaluated for injury. In the absence of brain parenchyma damage, the dura should be closed primarily when possible. Larger dural tears may require dural grafts.
- CSF leak
 - Small CSF leaks can be managed with bed rest.
 - Larger CSF leaks may require external drainage.
- Donor-site contour deformities
 - Rarely, a cosmetic problem (widened scar) when donor site is in hair-bearing scalp.
 - Burring down sharp edges of graft site can help camouflage defect.

Section IV: Skull Base and Midface

8 Free Fibula Flap for Midface Reconstruction

CHAPTER

J. Rodrigo Diaz-Siso and Eduardo D. Rodriguez

DEFINITION

- Composite midface defects, involving skin, bone, and mucosa, are commonly the result of oncologic resection, high-energy trauma, inflammatory diseases, or congenital anomalies.
- Unreconstructed midface defects may lead to impaired speech, oral incompetence, and limited masticatory, deglutitive, orbital, and respiratory functions, in addition to facial disfigurement and associated decreased quality of life.
- The free fibula is a versatile flap that can include a long segment of vascularized bone, which can be shaped as needed through multiple osteotomies.
 - The flap can include muscle, fascia, and/or skin, making it an ideal reconstructive option for composite defects.
- The reconstructive goals are to replace the facial buttresses, resurface internal and external soft tissue lining, separate the oral and nasal cavities, and restore the alveolus, resulting in a patent nasal airway, adequate midfacial projection and ocular globe position, and allowing for endosseous dental rehabilitation.

ANATOMY

- The skeletal foundation of the lower leg is composed of the tibia (medial) and fibula (lateral), parallel long bones connected by an interosseous membrane,

which divides the leg into anterior and posterior compartments (**FIG 1**).

- The anterior compartment is bordered laterally by the anterior intermuscular septum. The anterior tibial vessels and deep peroneal nerve are directly anterior to the interosseous membrane.
- The lateral compartment, which includes the peroneus longus and peroneus brevis muscles, is bordered posteriorly by the posterior intermuscular septum, which contains the perforator vessels that perfuse the lateral skin of the lower leg, and thus the skin island of the flap when applicable.

FIG 1 • Cross section of the middle leg showing fascial compartments and relevant anatomical structures.

- The deep posterior compartment includes, from medial to lateral: flexor digitorum longus, tibialis posterior, and flexor hallucis longus muscles; the fibular vessels run between the latter two. The posterior tibial vessels and

tibial nerve are found lateral to the flexor hallucis longus, posterior to the tibialis posterior muscle, and anterior to the transverse intermuscular septum.

- The posterior compartment includes the soleus and gastrocnemius muscles.
- The fibula is nonweight bearing, but the proximal and distal epiphyses are crucial to the integrity and stability of the knee and ankle joints, respectively.
- The common fibular nerve wraps around the neck of the fibula before dividing into the deep and superficial fibular nerves, limiting proximal dissection and procurement. Even after epiphyseal preservation, approximately 25 cm of vascularized bone can be harvested.
- The fibular artery provides the dominant blood supply to the fibula, supplemented by periosteal and muscular branches; the vascular pedicle can be considerable, yielding up to 15 cm. The well-defined vascular supply allows the division of the free fibula into segments as small as 2 to 3 cm.
- The two venae comitantes of the fibular artery are responsible for venous drainage.
- The lateral sural nerve supplies the sensory innervation of the lateral leg skin; sensory nerve coaptation is possible, but not routinely performed.
- Muscles commonly included in a free fibula flap include the flexor hallucis longus and the tibialis posterior, located in the deep posterior leg compartment. The soleus, located directly posterior to the posterior and transverse intermuscular septa, can also be included.
- The midface contains three vertical and two horizontal skeletal buttresses¹ (**FIG 2**).

FIG 2 • Illustration of the horizontal and vertical skeletal buttresses of the midface.

- Vertical: The nasomaxillary, zygomaticomaxillary, and pterygomaxillary buttresses maintain facial height and resist occlusal load.
- Horizontal: The inferior orbital rim maintains the position of the ocular globe, and together with the maxillary alveolus and the malar prominence, it is responsible for maintaining the facial profile and width, respectively.
- A classification of skeletal midface defects focuses on the absence of these essential functional subunits of the maxilla² (**FIG 3**):
 - Class I: unilateral dentoalveolar defect
 - Class II: unilateral dentoalveolar and orbital rim defect
 - Class III: bilateral dentoalveolar defect
 - Class IV: bilateral dentoalveolar and orbital rim defect
- Depending on concomitant skin deficits, and/or pterygoid injury, which affects

the complexity of the posterior fixation of the flap, this classification is designed to determine flap selection for microsurgical reconstruction.²

- Important: instead of attempting to recreate the absent curvilinear structures of the facial skeleton, segments of vascularized bone are strategically placed to serve as girders that are capable of (and necessary for) preserving function and maintaining aesthetic facial proportions and contour.³

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed medical history must be performed to identify patients with current or prior peripheral vascular disease, deep vein thrombosis, vasculitis, or lower leg trauma, which may increase the risk of an unreliable fibular vascular pedicle.
- The popliteal, dorsalis pedal, and posterior tibial pulses are examined.
 - Lower extremity Allen test can be performed to ensure that both the dorsalis pedis and posterior tibial arteries perfuse the distal lower extremity.
 - Anatomic variations, like peronea magna (hypoplasia or absence of anterior and posterior tibial arteries), must be identified⁴ (**FIG 4**).
- The range of motion and stability of the knee and ankle joints are assessed.
- Facial anthropometrics are assessed, including horizontal thirds and vertical fifths.
- Dental/facial midlines, dental show at rest and smiling, and maxillomandibular occlusal relationships are recorded when applicable.

IMAGING

- Angiography is not routinely performed but can be considered if history is positive for possible tibial artery damage or injury, and/or if distal pulse assessment is abnormal or suspicious.
 - Other imaging modalities (CT or MR angiography) are also effective alternatives.
- In traumatic defects, three-dimensional maxillofacial CT will allow precise analysis of the missing bone that will be reconstructed, in addition to soft tissue analysis.
- When computerized surgical planning (CSP) is employed, three-dimensional lower leg- and maxillofacial CTs are performed to aid the design of the flap, which is based on an existing traumatic defect or the predicted absent maxillary bone that will result from planned ablative surgery.

Class I

Class II

Class III

Class IV

FIG 3 • Classification of midface skeletal defects in ascending order of reconstructive complexity, and illustrations of possible free fibula flap reconstruction of each defect. Class I: Unilateral dentoalveolar defect. Class II: Defect involves inferior orbital rim and ipsilateral maxilla. Class III: Bilateral dentoalveolar defect. Class IV: Defect involves bilateral dentoalveolar loss and at least one orbital rim.

FIG 4 • Algorithm to rule out aberrant lower extremity vascular anatomy in a free fibula flap reconstruction candidate.

NONOPERATIVE MANAGEMENT

- Prosthetic obturation is among the earliest techniques developed to reconstruct facial defects.
- Midfacial prostheses can be considered in patients who are poor candidates for—or unwilling to pursue—free tissue transfer.
 - Advanced age, medical comorbidities, smokers, contaminated wounds, etc.
- In pediatric patients, prosthetic obturation can serve as a temporary reconstructive solution during growth.
 - Permanent free flap reconstruction can be revisited once the patient reaches skeletal maturity.

SURGICAL MANAGEMENT

- Reconstruction of composite midface defects may not be possible in a single stage; surgical plans and patient expectations must be managed with this in mind.
 - Phase 1 goals: restore skeletal anatomy, eliminate dead space if necessary, and deliver soft tissue volume in slight excess for future refinement.
- Consider early involvement of dental colleagues:
 - Close collaboration and detailed planning of osseointegrated implant placement is essential to optimizing dental rehabilitation and long-term outcomes.

Preoperative Planning

- VSP can accurately predict and facilitate fibular osteotomy and flap inset sites based on 3D reconstructions of CT data (**FIG 5**).
 - 3D-printed osteotomy guides ensure maximal precision during separation of the fibular segment from the lower leg, division of the bone flap into multiple segments, and fixation of the resulting segments to accommodate a desired flap shape.
- VSP also identifies the best point of fixation on the midface, in addition to aiding the design of recipient-site osteotomies that may be required prior to

optimal flap inset and fixation.

- A 3D-printed model of the patient's skull and the desired shape of the bone segment(s) help preoperative contouring of a 2.0-mm titanium miniplate, minimizing ischemia time. If required, minor adjustments in the shape of the plate can be made prior to flap inset.
 - Alternatively, stereolithographic models of the patient's facial skeleton and remaining dentition can be used intraoperatively for this purpose.
- Preferred recipient pedicles are the superficial temporal and facial vessels.
 - Unilateral defects: whenever possible, ipsilateral vessels are preferred.
 - Bilateral defects: less relevant; will depend on quality of local tissues; may determine recipient site selection.
 - Class IV defects (bilateral dentoalveolus and inferior orbital rim): multiple free flaps may be indicated; bilateral recipient vascular pedicles will likely be necessary.
- When choosing between ipsilateral and contralateral donor fibula, consider the following:
 - The fibular vessels are located on the medial surface of the fibula, and the flap's vascular pedicle extends superiorly from the proximal end of the procured bone segment.
 - Thus, the fixation plates will be screwed onto the lateral surface of the fibula, which will become the anterior surface of the reconstructed midface bone (flap vasculature will run on posterior surface).
 - Recipient vessel selection may be limited in extensive defects, and vascular compromise of one leg may force the surgical team to procure the flap from the opposite side. Nevertheless, fibula flaps can be rotated 180 degrees to reach ipsilateral or contralateral recipient vessels depending on reconstructive needs.
 - A fibula flap ipsilateral to the chosen recipient vessels may be oriented more easily so that, upon inset, the donor vascular pedicle does not cross the midline to reach the recipient vessels.

FIG 5 • Computerized surgical plan to reconstruct a midface defect that resulted from the resection of a right maxillary oncologic deformity in a 58-year-old man. **A.** Synthes ProPlan software was used to calculate the overall length of the fibula segment to be elevated, as well as the length of each fibula segment to be osteotomized and reshaped before flap inset. **B.** Patient's preoperative anatomy showing the right

maxillary defect, and the virtually planned postoperative result with the fibula segments recreating the horizontal maxillary buttresses.

- This limits interference with anesthesia and decreases the required length of the flap's vascular pedicle.
- For unilateral soft tissue defects, determine/anticipate the extent of absent skin vs floor of mouth.
 - If more external skin is required, the skin paddle from an ipsilateral fibula flap may lie more favorably upon inset.
 - If more floor of mouth tissues are required, a contralateral fibula flap may be more favorable by extending the skin paddle resection posteriorly.

Positioning

- The patient is positioned supine, with the knee of the donor leg flexed, the pelvic girdle rotated internally, and with towels or a sandbag elevating and stabilizing the heel.

Approach

- A two-team approach to reconstruction is used whenever possible.
 - One team elevates the flap while the other explores the midfacial defect.
- Early reports describe a posterior approach,⁵ but lateral surgical approach has proven simpler and quicker.

TECHNIQUES

■ Preparation of Midface Defect

- The mechanism of injury will determine the extent and complexity of defect preparation.
- Mass resection: the defect is created by the ablative surgery team.
 - Reconstructive team must precisely assess the resulting skeletal and soft tissue requirements before finalizing and/or adjusting previous flap design if necessary.
- High-energy trauma: early reconstruction is advocated.

- Aggressive debridement of nonviable tissues is necessary to determine the eventual defect.
 - Reconstruction before scar formation and contracture (within 2 weeks) facilitates dissection, precise skeletal alignment, and maintains adequate volume of the soft tissues.
 - Delayed reconstruction is approached as a secondary reconstruction, requiring defect recreation, scar tissue removal, skeletal realignment, and soft tissue reexpansion.
 - Necessary corrective osteotomies or skeletal realignments are performed at this time to streamline bone inset.
 - VSP dental positioning guides are fixated to determine and maintain occlusion during surgery.
 - VSP osteotomy guides are fixated onto applicable bone sites.
 - Osteotomies are performed using an oscillating saw.
 - Guides are removed.
-

■ Free Fibula Flap Harvest: Lateral Approach

Donor Site Marking

- Once the donor site has been selected, as described in Preoperative Planning, the fibula is outlined and marked by palpating the fibular head, the lateral malleolus, and the anterior and posterior fibular borders on the lateral leg (**TECH FIG 1**).
- The most proximal 5 to 7 cm of the fibula is marked; this segment is usually not be included in the flap to avoid injury to the common peroneal nerve during dissection and to prevent postoperative knee instability.
- The distal-most 5 to 7 cm of the fibula is also measured, marked, and excluded from the flap to avoid ankle instability.
- The fibular segment that will be included in the flap is marked as distally as possible to maximize (proximal) pedicle length.
- A Doppler pencil probe is used to identify skin perforators within the posterior intermuscular septum, located in close proximity to the posterior border of the fibular outline.
- The skin paddle is designed and marked on the distal two-thirds of the lateral leg, ensuring that a perforator emitting a prominent signal is located in the center of the flap area.

- Flap procurement is performed after partial exsanguination and placement of a thigh tourniquet, which is inflated to 100 mm Hg higher than the patient's systolic blood pressure.

Incision and Skin Paddle Dissection

- A mid-lateral incision is made posterior to the palpable fibula and skin flap is elevated above the fascia.
 - The superficial peroneal nerve lies in this layer, and care is taken to avoid injury.
- The anterior border of the skin paddle marking is incised; dissection proceeds in a posterior direction until the posterior intermuscular septum is identified (**TECH FIG 2**).
- The fasciocutaneous perforators that perfuse the flap are located in the posterior intermuscular septum, which is thin and fragile and must be dissected cautiously.

TECH FIG 1 • Surgical markings for free fibula flap elevation. Location of perforators is identified, and skin paddle marked accordingly. Proximal and distal 7 cm of the fibula are also marked and excluded from the flap.

- Dissecting medially, the peroneus longus and peroneus brevis muscles are sharply separated from the posterior intermuscular septum until the fibula is identified.

- The posterior margin of the skin paddle is incised and elevated anteriorly above the fascia until reaching the posterior intermuscular septum.

Lateral and Anterior Compartment Dissection

- Anterior to the perforators, the superficial muscular fascia is incised. Beginning inferiorly, the peroneal muscles are sharply dissected off the fibula.
 - To maintain periosteal circulation, a small cuff of peroneus brevis muscle is preserved on the fibula.
 - Superiorly, the common peroneal nerve is identified and preserved.
- The peroneal muscles are reflected anteriorly, and the anterior intermuscular septum is incised, accessing the anterior compartment.

TECH FIG 2 • Path of dissection of a free fibula flap that requires a skin paddle. The posterior

intermuscular septum is separated from the lateral compartment until the fibula is identified.

- The extensor digitorum longus and extensor hallucis longus are elevated from the fibula until the interosseous membrane is identified.
 - The anterior tibial artery and deep peroneal nerve lie anterior to the interosseous membrane.
 - Medial retraction of the lateral and anterior compartment musculature helps visualize and protect the neurovascular pedicle during dissection.
- The interosseous membrane is incised, resulting in anterior access to the deep posterior compartment and visualization of the tibialis posterior muscle (**TECH FIG 3**).

Posterior Compartment Dissection and Distal Osteotomy

- If soleus muscle is included in an osteomyocutaneous flap design, the lateral half of the soleus is separated posteriorly from the lateral head of the gastrocnemius.
 - When the midline of the soleus is reached, the dissection veers anterolaterally toward the fibula until the transverse intermuscular septum is identified.
 - Based on a separate muscular perforator, the lateral half of the soleus muscle can be elevated as part of a chimeric osteomyocutaneous flap design.
- If the soleus muscle is not included in the flap design, proceeding medially, the soleus muscle is bluntly separated from the posterior intermuscular septum until reaching the transverse intermuscular septum.
- In all cases, the transverse intermuscular septum is incised, resulting in posterior access to the deep posterior compartment and visualization of the flexor hallucis muscle (see **TECH FIG 3**).
- The custom osteotomy guide is fixated onto the lateral surface of the fibula.
 - Depending on individual patient needs and flap design, efforts are made to position the osteotomy guides favorably in relation to dominant skin perforators.
- The distal osteotomy is performed using an oscillating saw.

Deep Posterior Compartment Dissection and Proximal Osteotomy

- Anteriorly, the distal posterior tibialis muscle is transected at the chevron-shaped decussation of its fibers.
- Dissection proceeds in a proximal direction by exposing the peroneal vessels on the medial surface of the fibula and the flexor hallucis longus muscle posteriorly (see **TECH FIG 3**).
 - The amount of posterior tibialis muscle elevated with the flap can also be adjusted depending on recipient site soft tissue requirements, but at least a small cuff is preserved on the fibula to maintain periosteal circulation.
 - Gentle lateral retraction of the fibula can facilitate dissection and ligation of perforators emerging from the fibula.
 - The posterior tibial vessels and the tibial nerve can be visualized medially and avoided during dissection.
- The flexor hallucis longus muscle is carefully separated from the fibula in a proximal direction, exposing perforator branches.
 - To maintain periosteal circulation, a small cuff of flexor hallucis longus muscle is preserved on the fibula.
 - A larger lateral portion of the flexor hallucis muscle can also be elevated with the fibula if necessary.
- Perforator branches are cautiously dissected, ligated, and traced proximally to identify the proximal fibular vessels and the common peroneal nerve.
- The proximal osteotomy is performed, allowing mobility of the flap and excellent visibility of the proximal fibular pedicle, which is dissected until visualizing its branching point from the proximal posterior artery.

TECH FIG 3 • The path of dissection during elevation of a free fibula flap. *Red arrow* shows dissection of the lateral and anterior compartments and through the interosseous membrane. *Green arrow* demonstrates posterior compartment dissection in cases where additional muscle is not necessary. *Blue arrow* shows the path of dissection when soleus muscle procurement is warranted for coverage or soft tissue bulk.

Completion

- When applicable, osteotomies to reshape the elevated fibula are performed once the flap has been dissected in situ (**TECH FIG 4**).
- The proximal fibular vascular pedicle is ligated, and the flap can be

transferred to the back table for further customization.

- The tourniquet is removed and meticulous hemostasis is obtained.
- The skin flap donor site is skin grafted.
- Skin incision proximal and distal to skin paddle are closed primarily.

TECH FIG 4 • Elevated, osteotomized, and reshaped fibula flap with vascular pedicle still attached.

■ Free Fibula Flap Customization, Skeletal Fixation, and Inset

- The free fibula flap's versatility makes it applicable to different defect types (see **FIG 3**).
 - Small defects: can be reconstructed using a single linear bone segment (Class I).
 - Multiple osteotomies: the fibula can be fixated into a polygonal chain of bone segments that can be shaped to accommodate contoured defects (Class I, II, III, IV) or increase the vertical height of the flap (Class II, IV).
 - Soft tissue adaptability: multiple skin paddles based on individual

septocutaneous perforators can be created.

- Dead space obliteration: the flexor hallucis longus, tibialis posterior, or soleus muscle can be included with the flap.
- Mock bony inset can be performed in custom 3D-printed/stereolithographic model of recipient site skeletal anatomy, with adjustments made as needed (**TECH FIG 5**).
- The reshaped fibula is inset and fixated onto the recipient site bone using 2.0-mm miniplates using monocortical screws.
 - The skin paddle (with or without a muscular component) can be gently rotated based on the main perforator to achieve proper orientation.
- Donor and recipient vascular pedicles are approximated and length is trimmed to prevent kinking.
 - Anastomoses are preferably performed end-to-end with interrupted 9-0 nylon sutures. Venous couplers can also be used at the surgeon's discretion.
- Soft tissue inset
 - Internal or external points of compression to the anastomosis sites must be avoided.
 - Open or closed drains are used to avoid restrictive fluid collection.
 - Meticulous hemostasis is performed at recipient site to avoid active bleeding or hematoma formation.
 - Soft tissues and skin are closed.

TECH FIG 5 • Prior to full elevation, the fibula flap is inset onto a 3D-printed model of the patient's

craniofacial skeleton and maxillary defect, allowing the surgical team to verify that size and shape of the flap conform to the operative plan.

■ Anticipated Secondary Surgeries

- Phase 2+ goals: contour bone and/or soft tissues, and address position of adjacent subunits when applicable (eyelids, nose, etc.) using reconstructive surgery armamentarium.
- Neomaxilla may require distraction or stabilization.
- Flap soft tissues may require debulking procedures.
- Cheek soft tissues may require augmentation via fat grafting or additional free tissue transfer.
- Maxillary defects involving the dentoalveolus and the inferior orbital rim (Class II and IV) may require additional soft tissue augmentation in the periorbital and malar regions.

PEARLS AND PITFALLS

Indications

- Anticipate the need for multiple stages and incorporate secondary surgeries into reconstructive plan
- The full extent of the defect and precise composite tissue requirements must be defined before initiating flap elevation
- Early intervention is essential in high-energy traumatic defects

Flap design

- The ample bone can be osteotomized and reshaped to reconstruct a variety of composite midfacial defects
- Focus on functional structural support, not exact replication of absent bone
- Muscle can be included to obliterate dead space
- Generous skin paddle can be elevated based on septal perforators

Approach

- Employ efficient two-team approach
- Protect the common peroneal nerve proximally
- Exclude proximal and distal fibular segments to prevent knee and ankle instability

Computerized surgical planning	■ Facilitates precise design of the bone segment ■ Predicts corrective osteotomies at recipient site for snap fit ■ Streamlines bone inset and fixation ■ Reduces ischemia time
Watertight soft tissue closure	■ Avoid communication with oral cavity
Postoperative management	■ Avoid restrictive dressings in head and neck ■ Administer DVT prophylaxis if not otherwise contraindicated ■ Close monitoring of hemodynamic stability and flap viability ■ Open communication with postanesthesia and/or ICU team to avoid vasopressor therapy or compression whenever possible

POSTOPERATIVE CARE

- Patients often remain intubated up to 48 hours after surgery to prevent early respiratory complications due to airway secretions or edema.
 - This expedites emergent returns to the operating room.
- Strict monitoring of hemodynamic status, urine output, and fluid balance is mandatory.
 - Vasopressors are avoided unless other interventions such as fluid boluses, etc. have failed to stabilize the blood pressure.
- Deep venous prophylaxis is useful in most patients. However, concomitant injuries or intracranial surgery may be a relative contraindication and should be coordinated with anesthesia and the other surgical teams.
- Dressings and other restrictive materials are preferably avoided in the head and neck.
- Assessment of the flap's skin island must be aggressive to increase the likelihood of salvage in the case of vascular compromise, particularly in the first 24 to 48 hours.
 - Clinical monitoring of color, temperature, and capillary refill.
 - Doppler pencil probe monitoring at the site of anastomosis or available exposed surfaces.
 - First 24 hours: every 30 to 60 minutes.
 - Postoperative day 2 to 3: every 60 minutes.
 - Subsequent days until discharge: every 6 hours.
- Donor site:
 - The donor leg is placed in a boot or posterior splint with the ankle at 90

degrees, a monitor for signs of vascular insufficiency or compartment syndrome.

- Suction drains are evaluated daily and removed once less than 30 mL of serum is collected in 24 hours.
- There will be no ambulation initially, and the leg will remain elevated until the skin graft is fully healed.
- Upon ambulation, partial weight bearing will gradually transition to full weight bearing.
- Bone union and position can be assessed with serial CT scans (**FIG 6**).

FIG 6 • Postoperative CT and photograph of the patient in **FIG 5**. CT image shows that the operation has been performed according to the virtual plan, resulting in successful restoration of midface contour.

OUTCOMES

- In Chang et al.'s series of 116 free fibula flaps, increased rates of partial flap loss and total complications were recorded for ischemia times exceeding 5 hours (tourniquet plus microvascular clamp).⁶
- Marre found a higher risk of vascular compromise after 1.5 to 2 hours of ischemia time in a series of 182 deep inferior epigastric perforator flaps.⁷

- Seruya et al. compared CSP-assisted (10) vs conventional (58) free fibula flap craniofacial reconstruction.⁸
 - Short- and long-term outcomes were comparable.
 - Total ischemia time was significantly shorter in CSP group; total operative time was shorter but not significant.
- Avraham et al. reported high rates of dental rehabilitation, increased reconstructive complexity, and decreased total operative time in a series of 54 CSP mandibular reconstructions.⁹
- Ch'ng and colleagues described a series of 54 patients receiving a free fibula flap to reconstruct the maxilla or mandible and subsequent osseointegrated implant dental rehabilitation after oncologic resection.¹⁰
 - Of 243 implants, 91.8% were retained at median 3-year follow-up.
 - Risk of implant failure without radiation was 5.1%.
 - Failure when implants were placed after radiation was 13%.
 - Failure when implants were placed before radiation was 18.6%.

COMPLICATIONS

- Up to 30% overall donor site morbidity has been reported.
 - Infection
 - Wound dehiscence
 - Skin graft failure
 - Paresthesias distal to donor site
 - Great toe flexion contracture
 - Tibial curvature/valgus deformity in children
- Recipient site complications:
 - Infection
 - Hematoma
 - Lower eyelid ectropion (delayed reconstruction)
 - Nonunion of the neomaxilla
 - Arterial or venous thrombosis requiring return to the operating room
 - Partial or total free flap failure

9 Soft Tissue Flaps for Maxillary Reconstruction

CHAPTER

Ahmed M. Hashem and Brian R. Gastman

DEFINITION

- Maxillary reconstruction is the process of rebuilding and coverage of midface and cheek defects.
- Tissue loss often results from oncologic resections but can also occur secondary to blunt or penetrating trauma and, less commonly, from necrotizing infections.
- The loss of critical soft tissue components such as the lower eyelid, the nose, the upper lip, and oral commissure adds significant complexity to the reconstruction.
- The functional implications involve speech, mastication, and deglutition.

ANATOMY

- The maxilla is a complex structure occupying the midface.
- Conceptually, it is a six-walled construct (hexahedron) bounded by the orbit superiorly, the palate and oral cavity inferiorly, the nasal airway medially, and the infratemporal fossa and cranial base posteriorly.
 - Anteriorly and laterally, it forms the contour of the cheek (**FIG 1A,B**).¹
- The maxillary sinus is a mucosa-lined air cavity in the maxillary process that drains into the middle meatus of the nose.
 - The sinus is rudimentary at birth but undergoes rapid expansion 6 to 7 years after puberty.
- The skeletal framework consists mainly of the maxillary and zygomatic bones, which articulate with parts of the pterygoid, palatine, lacrimal, ethmoid, and sphenoid bones (see **FIG 1A**).
- The vertical maxillary buttresses and the horizontally oriented alveolar process

define the contour of the midface, contribute to vertical facial height, carry the dental elements of the upper jaw, and support the upper lip.¹

- The soft tissues comprising the skin, lining mucosa, and intervening facial musculature constitute the lower eyelid, the cheek, the upper lip, and oral commissure.¹
- From a reconstructive standpoint, it is critical to appreciate that the maxilla forms the floor of the orbit, the roof of the mouth (the palate), and the lateral nasal wall including the lacrimal system.¹
- From a functional perspective, its integrity is critical for normal speech, mastication, and deglutition.¹

FIG 1 • A. Left maxilla (frontal view). Bony articulations of the maxilla. The maxilla shares in the formation of the orbital floor and forms the lateral nasal wall. **B.** Right maxilla (inferior view). The maxilla forms the roof of the mouth (the palate) and is related posteriorly to the infratemporal fossa and cranial base. **C.** Right maxilla. The maxilla is related to the critical facial muscles (orbicularis oculi, orbicularis oris, levators of the upper lip) and the frontal, zygomatic, and buccal rami of the facial nerve.

■ Anteriorly, it is related to the facial and angular arteries, whereas posteriorly, it

is in close proximity to the internal maxillary artery, the pterygoid venous plexus, and the last four cranial nerves.

- The zygomatic and buccal branches of the facial nerve ramify in the sub-SMAS plane of the cheek to supply the orbicularis oculi, the orbicularis oris, and the levators of the upper lip (**FIG 1C**).
- The infraorbital nerve travels in the floor of the orbit to emerge on the cheek through the infraorbital foramen and provide sensation to the midface. The zygomaticofacial nerve also appears anteriorly through a foramen inferior to the lateral part of the inferior orbital rim.

PATHOGENESIS

- Maxillary defects occur in many cases secondary to tumor extirpation of malignancies originating in the paranasal sinuses, the nasal cavity, the palate, or the orbit.
- In other cases, aggressive malignancies arising from the intraoral mucosa, the cheek skin, or the salivary glands may invade the maxilla and require extensive composite tissue excisions.¹
- High-energy traumatic injuries (eg, gunshot wounds) constitute another cause of challenging maxillary defects.²
- Necrotizing inflammations like noma (cancrum oris)³ and malignant pyoderma in association with granulomatosis with polyangiitis have also been described.⁴
- Composite resections where lining, support, and external skin are missing can pose a significant reconstructive challenge.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history should be obtained to identify comorbid conditions that may be optimized preoperatively.
 - A personal or family history of clotting/bleeding abnormalities should be elicited.
 - History of prior surgery, neck dissection, or radiation therapy of the head and neck should be noted.
- Physical examination of the head and neck should evaluate dentition, speech and swallowing, facial nerve function, and sensory innervation.
 - Changes in skin texture and quality, eyelid function and support, and mouth opening should be assessed.
- The expected resection should be envisioned and soft tissue and bony requirements estimated. Close collaboration with the ablative surgeon is crucial

in this regard.

- Assessment of potential local and distant tissue donor sites should be undertaken (eg, temporalis, pectoralis major, radial forearm, rectus abdominis, anterolateral thigh [ALT] flap).
- Allen test is useful for evaluation of the palmar arch in patients who may require a radial forearm flap.
- Assessment of soft tissue thickness and previous scars/surgery is important to identify first-line and second-line choices for reconstruction.

IMAGING

- Imaging modalities like CT scan and MRI are useful preoperatively to determine the size and extent of the tumor and understand the potential resulting defect. These studies are also useful in patients with acquired defects of the maxilla resulting from trauma or infections.
- A 3D CT scan helps with preoperative virtual surgical planning and manufacturing of custom-designed models, templates, osteotomy guides, and prebent plates and selection of optimum screw size and site especially if dentoalveolar reconstruction and functional occlusion are contemplated. However, these options are most useful for osseous reconstruction of maxillary defects.
- Duplex examination or CT angiography with 3D reconstruction is occasionally required to evaluate the neck vessels in difficult cases with prior neck dissection or radiotherapy.
- Postoperatively, positron emission tomography (PET) and CT scan will be of benefit to assess the operative bed for tumor recurrence if a free flap was employed.

NONOPERATIVE MANAGEMENT

- Custom-made obturators can be used to manage maxillary defects and can provide support for facial structures and separate the oral cavity from the maxillary sinus.
- Obturators restore intelligible speech, prevent nasal regurge, and provide aesthetic contours.
- Obturators may be useful in patients at high risk for complex reconstructive procedures or, on occasion, as salvage of a failed reconstruction.
- They may also be useful for small defects of the palate (<50% of the hard palate), providing rapid rehabilitation with no donor-site morbidity.

- In general, obturators are best for small defects in the hard palate and are more difficult to secure in larger defects that involve the hard and soft palate.
- Larger defects are more easily managed with free flaps resulting in superior restoration of speech and swallowing^{5,6}
- The use of an obturator requires close preoperative, intraoperative, and postoperative collaboration between the oncologic surgeon, reconstructive team, and a prosthodontist. The steps necessary for obturator creation include:
 - Fabrication of dental casts, analysis of occlusion, and preoperative modeling
 - Creation of a temporary obturator manufactured from heat-processed polymethylmethacrylate, which is strong enough to provide a stable and functioning construct but is still adjustable intraoperatively using a bur or drill to fit the surgical defect
 - Split-thickness skin grafting of the buccal surface of the cheek flap and bolstering with the temporary obturator, which is fixed with screws or wires
 - Postoperative evaluation and adjustments
 - Fabrication of a permanent prosthesis fashioned from durable cast metal base (eg, titanium) after maturation of the surgical cavity and conclusion of radiotherapy
- Use of obturators carries the advantage of visual inspection of the surgical site for tumor recurrence. This benefit, however, remains theoretical because reoperation is infrequent and modern imaging enables early detection. Nevertheless, many patients have been successfully served with these devices.
- Disadvantages of obturators include leakage and nasal regurgitation due to imperfect fitting, the need for frequent cleaning and successive refinements as the tissues remodel.

SURGICAL MANAGEMENT

- The development of microsurgical techniques enabled successful autogenous tissue reconstruction of complex maxillary and midface defects.
- The approach is largely dictated by the extent of the defect and the functional requirements.
- Simple defects can be closed with local soft tissue flaps and bone grafts when necessary and rarely pose a problem.
- Complex composite defects involving external skin cover, structural support, and lining require planning for restoration of orbital floor support, lining of the nasal airway, palatal reconstruction, and resurfacing of surface defects that may include the upper lips, eyelids, and nose. In addition, dental restoration is

necessary in most maxillary resections that involve the hard palate.

- In this context, the classification system described by Cordeiro and Santamaria¹ is useful to stratify maxillary/midface defects and evaluate their functional requirements. The resultant analysis is able to guide appropriate treatment strategies.¹ Based on this schema, maxillectomy/midface defects can be categorized as follows:
 - Type I defect (limited maxillectomy): Only one or two walls—*excluding the palate*—of the hexahedron are missing. Usually, there is an absence of the anterior wall in conjunction with either the medial wall or the floor of the orbit (**FIG 2**).¹
 - Type II defect (subtotal maxillectomy): The whole lower maxilla is absent (the dentoalveolar arch, the anterior, medial, and lateral walls, in addition to the palate), while the orbital floor is intact.
 - These are further subdivided into type II-A when less than half of the transverse hard palate is missing and type II-B when more than half of the transverse hard palate is resected (**FIG 3**).
 - Type III defect (total maxillectomy): The whole maxilla including the orbital floor is deficient. Type III defects are additionally split into type III-A if the orbital contents are preserved and type III-B if they are exenterated (extended maxillectomy) (**FIG 4**).¹
 - Type IV defect (orbitomaxillectomy): The orbit and maxilla are removed while sparing the palate. This may include resection of the anterior cranial fossa leaving the dura or brain exposed (**FIG 5**).¹
- The advent of vascularized composite allotransplantation (ie, facial transplantation) refined midface and maxillary reconstruction by replacing “like” with “*exact* like,” thus achieving a closer aesthetic match in terms of soft tissue and skeletal components.
- The risks of lifelong immunosuppression nevertheless limit the use of this modality, which is still considered experimental, to a highly select group of patients (eg, trauma).
- Gastman et al. published an extension of Cordeiro and Santamaria classification system¹ to address the added specific needs in evaluating patients presenting for facial vascularized composite allotransplantation.⁷

FIG 2 • In a type I (limited maxillectomy) defect, the anterior and medial walls are missing and occasionally the orbital floor; the palate is intact.

A

B

FIG 3 • Type II (subtotal maxillectomy) defect involves the lower maxilla including the palate. In type II-A, less than half of the transverse palate is missing. In type II-B, more than half of the transverse palate is resected.

FIG 4 • Type III (total maxillectomy) defect. In type III-A, orbital contents are preserved. Type III-B is associated with orbital exenteration (extended maxillectomy).

FIG 5 • In a type IV (orbitomaxillectomy) defect, the upper maxilla and orbit are missing, while the palate is intact.

Preoperative Planning

- Oncologic resections are by far the most common cause of maxillary defects. Consequently, adequate tumor clearance and tumor-free margins assume the highest priority in management. Close collaboration with the ablative surgeon is thus critical.
- Resections may involve functional impairment of speech and oral intake in addition to loss of globe support and eyelid cover.
- The reconstruction is best accomplished in a multidisciplinary setting with input from surgical oncology, medical oncology, radiotherapy, speech, nutrition, ophthalmology, and dentistry, in addition to reconstructive surgery.
- Complex defects are often composite and require three-dimensional planning to reconstruct lining, cover, and provide structural support. Accurate analysis of the functional needs is hence crucial. Accordingly, precise assessment of the extent of prospective resection based on clinical and imaging data should be undertaken.
- Adjacent critical soft tissue components including the eye, lip, oral commissure, and nose are evaluated.
- The neck is examined for previous scars and the availability of ipsilateral suitable recipient vessels.
 - Supplementary Doppler examination can be helpful. In case of any doubt, a CT angiogram with 3D reconstruction can clarify the vascular status in the cervical region.
 - Occasionally, the superficial temporal vessels are spared and can serve as recipient vessels near the defect, which facilitates the microsurgery.
- Potential donor sites are evaluated for vascularity and adequacy, the pedicle length is measured, the skin paddle is determined, and the potential for primary donor-site closure is gauged.
 - Allen test is essential if a free radial forearm flap is contemplated.
 - CT angiography is occasionally necessary to assess donor vessels for other soft tissue flaps such as the ALT or rectus flap.
- In type II and III resections, the quality of dentition is assessed, the occlusion is analyzed, and impressions of the maxillary dental arch and palate can be

taken to create stone casts.

- Alternatively, computer-aided virtual surgical planning and 3D printing can provide computer-generated templates. These guides are helpful for osseous reconstruction of maxillary defects but are less useful in soft tissue reconstruction.

Positioning

- The resection is usually accomplished in supine position with the head rotated to provide greater access.
- A shoulder roll can be placed between the spine to extend the neck and facilitate dissection of recipient vessels.
- Flaps harvested in this position (eg, free radial forearm flap, free rectus abdominis flap, free ALT flap) are advantageous for a two-team approach to conserve operative time.

Approach

- Ideally, donor-site dissection is started at the same time as the ablative procedure. If there is uncertainty regarding the extent of the disease, it is wiser to wait until the margins are clarified. The technical details for each flap donor site are described elsewhere.
- In dentoalveolar defects, simultaneous insertion of osseointegrated dental implants at the time of osseous free flap reconstruction will optimize chewing, speaking, and swallowing at an earlier date.^{8,9} Patient selection however is crucial because subsequent radiotherapy can result in a high failure rate with this approach.¹⁰

TECHNIQUES

■ Limited Maxillectomy for Type I Defect

- In these defects, the anterior and medial walls of the maxilla with or without the orbital floor have been resected and require reconstruction (note that palatal involvement converts the condition to either a type II or type III maxillary defect) (see **FIG 2**).
- Functionally, the lower eyelid and occasionally the upper lip and portions of

the lateral aspect of the nose are also missing and need reconstruction.

- These are usually small-volume defects with large surface area requirements.
- The bony needs are limited to orbital floor to provide globe support and avoid dystopia. This does not necessitate vascularized bone nor a biomechanically high load construct. Thus, a bone graft enveloped in the free flap tissue is usually sufficient.
- The free radial forearm fasciocutaneous flap is generally suitable in this setting. It supplies relatively less bulky tissue and can harbor two skin islands (one for external cover and the other for nasal lining). The flap can be de-epithelialized to provide matching contour and envelope bone grafts for orbital floor support.
 - Alternatively, an osteocutaneous design can be used to supply vascularized bone and minimize bone resorption.
- The reconstruction proceeds with analysis of the defect after oncologic resection and planning of the flap taking care to estimate the length of the pedicle necessary to reach recipient vessels as well as the size of the internal and external skin paddles.
- Recipient vessels in the neck or superficial temporal vessels are dissected and made ready for microanastomosis.
- If orbital floor reconstruction is required, a template of the defect is created using a cardboard or foil material (the wrapper for chromic sutures is ideal).
- This template is then used to harvest an iliac crest or split calvarial graft.
 - The inner table of the iliac crest is preferable in most cases due to its increased thickness and natural curve.
 - However, if a calvarial bone flap has been raised by neurosurgery during the resection, a bone graft can also be easily harvested from the inner table.
- The bone graft is used to repair the orbital floor defect and fixed into place using miniplates (preferably self-tapping) or wires.
- A subcutaneous tunnel is created to pass the pedicle for the flap to the recipient vessels.
- The radial forearm flap is dissected as outlined in the flap harvest section and allowed to reperfuse for 20 to 30 minutes once the tourniquet is taken down.
 - The pedicle vessels are marked with blue dye to facilitate tunneling of the vessels and prevent twisting or kinking in this process.
- Once the pedicle length, suitability of recipient vessels, and hemostasis are

ensured, the flap is disconnected and brought up to the head and neck.

- The pedicle vessels are carefully passed through the tunnel taking care to avoid twisting.
- The flap is then carefully inset into the defect (either completely or partially) to set the length of the pedicle.
- Microsurgical anastomosis is performed in the standard fashion.

■ Subtotal Maxillectomy for Type II Defect

- This defect involves the lower maxilla, including the palate (see **FIG 3**).
 - Defects of the hemipalate in which the anterior projection of the maxilla is maintained (ie, resection is posterior to the contralateral canine) can be reconstructed with soft tissue flaps. These are moderate-volume defects and, when using soft tissue flaps, in general require more tissues than a radial forearm flap (although this is possible in obese patients).
 - Defects of the anterior palate that result in loss of facial projection are best reconstructed with osteocutaneous flaps¹¹ or an obturator.
- The vertical rectus or ALT flaps are good options for soft tissue reconstruction of type II maxillectomy defects.
 - The donor site should be selected based on the anatomic features of the flap (thickness of the soft tissues) as well as volume requirements of the defect.
 - The ALT flap can be harvested with a portion of the vastus lateralis muscle that is used to obliterate the maxillary sinus. Similarly, a portion of the rectus muscle can be used in the same manner.
 - In general, the use of adipose tissues for volume restoration is preferred over muscle due to the loss of facial volume that will occur when the muscle atrophies.
 - Similarly, the use of a muscle flap alone in obese patients should be avoided if possible due to the expected atrophy of the muscle and loss of facial volume. In these cases, a radial forearm flap may be a better option.
- Passing the flap pedicle medial to the mandible (ie, behind the soft palate) is the shortest route to the recipient vessels in the neck. The superficial temporal vessels can also be used; however, this orientation can make the inset of the flap more difficult.
 - It is easiest to pass the pedicle through the tunnel prior to inseting the flap.

- The rectus or ALT flaps are usually oriented vertically to repair the palatal defect.
 - Usually, a skin paddle measuring 4 to 5 cm in width is needed for hemipalatal reconstruction.
 - The use of a very wide flap should be avoided as this results in a convex palate that complicates postoperative eating and dental rehabilitation.
 - The goal is to recreate the concavity of the palate; however, this is not always feasible with soft tissue flaps and may require secondary revision.

■ Total Maxillectomy for Type III Defect

Total Maxillectomy with Orbital Preservation for Type III-A Defects

- In this category of maxillary defects, the whole maxilla is missing including both the palate *and* the orbital floor (see **FIG 4**). The orbital contents are spared, however, and thus orbital floor reconstruction is necessary to avoid orbital dystopia and diplopia and preserve binocular vision.
- The reconstructive goals include orbital floor reconstruction, obliteration of orbitonasal and orbito-oral communication, palatal resurfacing, and restoration of malar contour and in some cases external skin cover.
- The orbital floor can be reconstructed using split calvarium or iliac crest grafts as outlined above.
 - These bone grafts are sandwiched between the preserved orbital contents cranially and a free flap caudally.
 - Alternatively, an ipsilateral temporalis muscle flap can be used to cover the inferior border of the bone graft and separate it from the maxillary sinus, while an obturator is used to manage the oronasal communication.^{1,12} This approach is probably best reserved for patients who are not suitable free flap candidates and who will not require postoperative radiation therapy.

Total Maxillectomy with Orbital Exenteration or Extended Maxillectomy for Type III-B Defects

- This defect includes the whole of the orbit and the maxilla in continuity (see **FIG 4**).
 - The anterior cranial fossa/roof of the orbit may be deficient with resultant brain or dural exposure requiring urgent coverage.

- The external soft tissue loss is often extensive and may encompass the eyelids, lateral nose, upper lip, and oral commissure.
- The reconstructive goals comprise restoration of nasal and palatal lining, coverage of brain or dura, and external skin cover if necessary.
- In type III defects, the malar projection will be maintained if the malar eminence is spared.
 - Otherwise, the soft tissue of the flap can be used to provide projection; however, this may atrophy with radiation and require revision surgery.¹
- To reconstruct the through-and-through defects and seal the orbit, single free flaps can be folded onto themselves to provide both external cover and internal lining.
- The selected free flap should fill the cavity of the maxillary antrum, obliterate any dead space, and possess multiple skin islands to provide nasal and palatal lining in addition to external skin cover.
- The free rectus abdominis myocutaneous flap has a robust and dependable blood supply.
 - The abundance of skin perforators permits versatility and yet reliability in designing multiple skin islands to address palatal and nasal lining in addition to external skin cover.¹² The pedicle length is usually sufficient to reach the ipsilateral neck and can be extended in select cases with more cranial defects to reach the neck without the need for vein grafts.¹³
 - The main drawback of this flap is the excess bulk in some patients that requires secondary debulking procedures.
 - Moreover, the flap does not provide vascularized bone to restore orbital floor support or allow dental implants (**TECH FIG 1**). Nevertheless, nonvascularized bone can be used for orbital floor reconstruction, and dental prostheses (eg, dentures) can be designed to optimize function.^{14,15}
- Lateral circumflex femoral artery–based flaps can also provide ample soft tissue and a long pedicle.
 - Multiple skin islands and muscle can be harvested on a single vessel using the transverse and descending branches.
 - Excess adipose tissue can create a bulky reconstruction, however.¹⁶
 - Like the rectus abdominis myocutaneous flap, this is a soft tissue flap, and nonvascularized bone grafts will need to be used (**TECH FIG 2**).
- The ALT flap based on the descending branch of the lateral circumflex femoral artery is particularly versatile in midface/maxillary reconstruction.

- To achieve sufficient pedicle length, it is necessary to dissect the vessel up to its takeoff from the lateral circumflex femoral artery.

TECH FIG 1 • **A.** Type III-A right maxillary defect following total maxillectomy with orbital preservation. The orbital floor (*black arrow*) and the palate (*blue arrow*) are missing and will need to be reconstructed. **B.** Elevation of a vertical rectus abdominis myocutaneous flap based on the inferior epigastric vessels (*black arrow*). The skin island (*red arrow*) is designed to fit the palatal defect. **C.** Showing the flap inset. The skin paddle was used to reconstruct the palate (*blue arrow*). The orbital floor was restored with

a titanium mesh (*black arrow*) that is sandwiched between the orbital tissue cranially and the free flap caudally. The muscle was used to fill in the dead space. **D.** Postoperative picture after closure of the skin incision.

TECH FIG 2 • A. Central face high-energy avulsive injury involving the mandible, the alveolar process, and the palate, in addition to the nose and cranial base. The *black arrows* point to the remnants of the mandibular arch, the *red arrows* point to the remaining

part of the posterior palate, and the *blue arrows* point to the cranial base. **B.** Harvesting of a free ALT flap designed to be tubed and folded to reconstruct the lateral nasal wall, the nasal floor, and the palate. The *black arrow* points to the vascular pedicle. The red dotted line denotes the axis where the flap will be folded to form the nasal floor on one side and the palate on the other. The red ellipse indicates the border that will be tubed to create a nasal passage. **C.** Early postoperative appearance after reconstruction. The lower lip and lower jaw were restored with a free osteocutaneous fibula flap.

- With a perforator design, it is usually possible to achieve enough length to reach the facial artery in the neck.
- If the superficial temporal vessels are intact and preserved, they constitute a reasonable alternative recipient. This simplifies the microsurgery.
- Prior to surgery, it is prudent to evaluate the thickness of the subcutaneous tissue of the lateral thigh, which is variable in different age groups, among both sexes, and according to body habitus and fat deposition.
- This is critical in maxillary/midface reconstruction, which frequently requires folding of the flap to accommodate the complex multiwalled nature of the maxilla (hexahedron).
- The design of the flap should consider the location of the pedicle in relation to the recipient vessels. Errors in design can render the reconstruction more challenging.
 - The flap can be easily folded upon itself to provide cover and lining of multiple surfaces (**TECH FIG 2B**).
- A suprafascial dissection can result in less bulk and is not much more challenging in harvesting the flap.
 - The advantage is a better thigh contour at the donor site especially if grafting is necessary.
 - On the other hand, inclusion of the deep fascia can be useful to substitute for absent dura in respective defects.
- The reconstruction with the ALT is often bulky and requires secondary

revisions to optimize appearance.

- The donor site rarely causes a problem even if a complex design is used.
- Free iliac crest with internal oblique muscle based on the deep circumflex iliac artery can provide vascularized bone to reconstruct the orbital floor and simultaneously provide sufficient bone stock for dental implants.
 - The internal oblique muscle tissue can obliterate the dead space and seal the oral and nasal communication.
 - Subsequent epithelialization of the muscle surface restores a near-normal lining.
 - Harvesting can be more difficult than other flaps, however, and the pedicle length is limited.⁵
- Flaps based on the subscapular/thoracodorsal axis constitute another alternative.
 - The latissimus dorsi, the serratus anterior, and the teres major can be harvested in conjunction with parts of the scapula nourished by the circumflex or angular branch, thus supplying plenty of muscle in addition to vascularized bone.
 - The skin can be included as a musculocutaneous or perforator-based flap.
 - Bone stock is less robust compared to the iliac crest free flap, but the pedicle is longer.
 - Although dissection is less challenging than the iliac crest free flap, the main drawback is that a two-team approach is not feasible. Furthermore, shoulder motion can be problematic in the early postoperative period.^{5,17,18}

■ Orbitomaxillectomy for Type IV Defects

- In these defects, the upper maxilla and orbit are missing while the palate is intact (see **FIG 5**).
 - Again, the brain or dura may be exposed and may need urgent coverage.
- The reconstructive goals include sealing of the anterior cranial fossa (to manage oronasocranial communication), restoring the nasal airway, reconstruction of the palate, obliteration of the maxillary sinus, and, in some cases, external skin cover.
- A multi-island free flap with large volume is needed to achieve these goals and fill the resultant dead space.
- The free rectus abdominis myocutaneous flap has several advantages as

described above.

- Most relevant is the potential to extend the pedicle length to reach the neck vessels in these more cranial defects.
- Lateral circumflex femoral-based flaps (eg, free anterolateral thigh flap) constitute a reasonable alternative since they possess a long pedicle, can include additional muscle and fascia, allow versatility in design, and supply plenty of soft tissue with limited donor-site morbidity.
- The rectus flap is oriented in the vertical fashion as described for type II defects, and the pedicle is passed medial to the mandibular border to the neck vessels.

■ Critical Soft Tissue Component of the Face

Upper Lip and Oral Commissure

- The upper lip and oral commissure can be involved in all types of maxillary defects.
- Reconstruction of the oral sphincter is extremely important from a functional standpoint to preserve oral competence and avoid drooling, which can be extremely disturbing.
- Currently, there is no satisfactory method to recreate the oral sphincter mechanism using tissues other than the lip itself.
- Use of the remaining tissue to reconstruct the oral sphincter in form of a lip switch procedure (Estlander flap or the Karapandzic flap) is therefore indicated in all these defects unless the defect involves greater than 80% of the lip.^{1,14,14}
- Incorporating the free flap tissue into the oral aperture will lead to oral incompetence, drooling, and worse functional outcomes.¹
- Microstomia is generally less disturbing than the sequelae of oral incompetence.¹

Eyelids

- The eyelids can be involved in type I, type III, or type IV defects.
- In type III-B and type IV defects, this will be part of the orbital exenteration procedure. Eyelid reconstruction in these cases would only serve to cover a prosthesis and generally yields poor results.
 - A glue-on type of prosthesis can provide a reasonable alternative.¹

- In other categories of maxillary defects, the eyelids are usually preserved, but ectropion is a common complication following free flap reconstruction. In these cases, a secondary tarsal strip, skin grafting, and canthopexy are required.

Nose

- Loss of nasal tissue to different degrees can be encountered in a variety of maxillary defects.
- Functional restoration of the airway is independent of aesthetic reconstruction of the external nose.
- Ipsilateral local tissues (eg, nasolabial flap, mucoperichondrial septal flaps) may not be available.
- Concomitant nasal reconstruction at the time of maxillary coverage may lead to poor outcomes.
- Either a prosthesis or alternative surgical procedures, such as contralateral forehead flaps or even a second free flap, can be employed in a delayed fashion.

PEARLS AND PITFALLS

Oral competence

- Maxillary defects that involve a significant excision of the lips or oral commissure risk the development of oral incompetence with poor function and constant drooling. If less than 80% of the upper or lower lip is missing, it is better to restore the oral sphincter by way of a lip switch procedure (Estlander flap or the Karapandzic flap) rather than simply incorporating the free flap into the lip, which will result in oral incompetence and worse functional outcomes. Microstomia is a risk though following a lip switch procedure especially if a large portion of the lip was excised and postoperative radiotherapy is administered. Nevertheless, microstomia is less problematic than constant drooling.¹⁹

Intraoral lining

- In composite defects extending to the oral cavity, restoring the intraoral lining is essential to a successful maxillary reconstruction. Using the more proximal tissue that is nearest to the vascular pedicle and has the most reliable blood supply for this purpose is advisable.¹² First, it sets the length of the pedicle for microvascular

	anastomosis, and second, it lowers the risk of major oral leakage. This permits early oral intake and avoids contamination near the microsurgical anastomosis with attendant risks of secondary hemorrhage. It is easier to manage loss of external coverage and employ a secondary flap than to treat a situation of major oral leak due to necrosis of intraoral lining with obligatory cessation of oral feeding, infection, and pending risks of secondary hemorrhage.
Dental rehabilitation	■ Preservation of the ipsilateral canine and at least one molar can be extremely useful for dental rehabilitation to allow the alignment and fixation of dentures. ■ Reconstruction of the palate to provide a concave surface facilitates dental rehabilitation and preparation of a denture in patients who undergo soft tissue reconstruction of the palate. Secondary revision with liposuction and skin excision is sometimes necessary to facilitate this process.
Ectropion	■ Providing sufficient skin for cheek reconstruction and anchoring the flaps to bone can help minimize this complication. A concomitant canthopexy or canthoplasty may also be helpful. ■ Secondary procedures such as skin grafting, a tarsal strip, or canthopexy/canthoplasty can ameliorate cases of postoperative established ectropion.
Orbital dystopia	■ Accurate reconstruction of the orbital floor at an appropriate clinical level and for optimum depth is mandatory to support the globe and avoid this complication. The inner table of the iliac crest and outer table of the calvarium have matching curvature and are sufficiently strong to avoid dislodgement during mastication. Fixation to the remaining bone can be challenging, and a tongue in groove technique can be helpful in this regard.¹⁴
Palatal lining	■ It is crucial to accurately measure the skin inset into the palate. The palatal skin should be smaller or equal to the defect to avoid prolapse of skin into the oral cavity and speech impairment. Suspending the flap to the cranial base can be a useful adjunct to avoid this complication.

POSTOPERATIVE CARE

- Free flap monitoring using clinical examination, Doppler, and infrared spectroscopy is mandatory since early intervention will maximize flap salvage.
- Care must be taken to avoid compression of the pedicle in the neck or in the preauricular area. Pillows should be used carefully (or not at all) to avoid wrapping around the neck and compressing the pedicle vessels. Similarly,

tracheostomy ties and other circumferential neck dressings should be avoided.

- Patients should be kept in a head-up posture and hemodynamic stability monitored.
- General tracheostomy care if applicable and nutritional support are essential.
- Speech, dental, and nutritional evaluation should ideally commence in the preoperative phase and rehabilitation started immediately postoperatively to optimize patient outcomes.

OUTCOMES

- Cordeiro and Chen retrospectively reviewed 100 flaps used for midface reconstruction following oncologic resections performed at the Memorial Sloan Kettering Cancer Center.¹⁴
 - Generally satisfactory outcomes were achieved in most patients with autogenous free flaps.
- Intelligible speech was restored in most patients who required palatal resection (43 of 44), especially when less than half of the palate was lost. They noted that preservation of the soft palate maximized speech outcomes and prevented velopharyngeal dysfunction.
 - When more than half of the palate was sacrificed, they recommended the substituting skin island to be accurately measured equal to or smaller than the defect to avoid intraoral prolapse. If needed, it can be anchored to the cranial base.^{1,14}
- Most patients (47 of 50) resumed an unrestricted or soft diet postoperatively.
 - Oral competence was preserved or restored in most maxillary defects requiring lip resection (11 of 12 patients) using a lip switch procedure.
 - Microstomia was encountered in 3 of 12 patients.¹⁴
- Mild vertical and horizontal diplopia was observed in 1 and 4 of 12 patients, respectively, following orbital floor reconstruction but led to minimal functional disturbances.^{1,14}
- Ectropion occurred in 10 of 21 patients but was usually mild or moderate (70% of cases).
 - Severe cases (30%) were improved with skin grafting, a tarsal strip procedure, or a canthopexy/canthoplasty.¹⁴
- Of 70 patients evaluated for aesthetic outcome, 41 were rated excellent (58.6%), 25 were judged as good (35.7%), and 4 were evaluated as fair (5.7%).
 - Aesthetic outcomes were largely dependent on the extent of outer skin

resection and whether eyelid, lip, or globe removal was necessary.¹⁴

COMPLICATIONS

- Free flap loss will usually require a secondary free flap.
- Ectropion
- Ocular dystopia
- Enophthalmos
- Velopharyngeal dysfunction
- Unintelligible speech
- Nasal regurgitation of fluid
- Drooling
- Microstomia
- Color and texture mismatch of external skin
- Bulky reconstruction

Section V: Mandible

10 Mandible Reconstruction With Fibula Free Flap Using CHAPTER CAD/CAM Techniques

Jamie Levine, David Hirsch, and Lawrence Brecht

DEFINITION

- Recent advances in imaging, computer-aided design/computer-aided modeling (CAD/CAM) software, and 3D printing technology have enabled virtual planning of complex 3D osseous reconstruction of head and neck defects.¹⁻⁵
- Using these methods, we can now prepare exact models and customized surgical devices that facilitate and simplify reconstruction. Virtual surgical planning and customized surgical templates decrease the learning curve for osseous reconstruction of head and neck defects while simultaneously improving the precision of reconstruction.⁶
- This is important because traditional methods for surgical planning of these reconstructions have a steep learning curve and even small errors can lead to poor outcomes.
- CAD/CAM virtual surgical planning also increases collaboration with oncologic and dental colleagues leading to a more unified plan. This approach allows development of more creative solutions for complex defects that ordinarily would be difficult to visualize preoperatively.^{7,8}
- This chapter will provide step-by-step planning for mandible reconstruction using the fibula flap with CAD/CAM planning. This approach can easily be modified for use with other osseous sources (eg, iliac crest, scapula, etc.) or for reconstruction of other osseous defects of the head and neck (eg, maxilla).

ANATOMY

■ Mandible

- The mandible is a complex 3D structure with two symmetric points of articulation at the skull base forming the temporomandibular joint (**FIG 1A**).
- The mandibular body and the curved mental protuberance contain 16 sockets to hold the lower teeth. The ramus and condyle form the articulation points with the skull base.
- The mandible has two foramina.
 - The mandibular foramen is located on the internal surface of the ramus and serves as the entry point for the inferior alveolar nerve.
 - The mental foramen is on the external surface of the mandibular body, below the second premolar. The inferior alveolar nerve exits the mandibular canal at this location and then becomes the mental nerve.
- The mandible serves as the attachment point for multiple muscles, including the muscles of mastication that help coordinate movement of the mandible with chewing.
- The blood supply of the central mandible is derived from multiple sources including the inferior alveolar artery and periosteal branches from the surrounding musculature.

FIG 1 • A. Anatomy of the mandible. **B.** Anatomy of fibula flap.

■ Fibula flap

- The fibula is the preferred choice for mandible reconstruction in most

patients^{7,9} because of the following characteristics: the bone has a dual blood supply (periosteal and axial) enabling complex shaping of the bone; there is a large amount of bone available (20–25 cm) enabling reconstruction of subtotal mandibulectomy defects; the vascular supply is consistent and large caliber; the bone stock is sufficient for dental rehabilitation; and finally, because the fibula can be harvested simultaneously with the oncologic resection.

- The dual blood supply of the fibula enables surgeons to perform multiple osteotomies to achieve the complex shape of the mandible. However, in general, segments are planned.
- The blood supply for the fibula is derived from the peroneal artery and vein (**FIG 1B**).
 - The pedicle length is variable and depends primarily on the amount of bone that is needed and anatomic variability in the take off of the peroneal artery/vein from the tibioperoneal trunk. In general, the length of the pedicle can be planned preoperatively using virtual surgical planning and angiography.

PATHOGENESIS

- CAD/CAM virtual surgical planning can be used for acquired and congenital defects of the mandible. The most common cause of mandibular defects necessitating vascularized bone transfer is oncologic resection of the mandible for malignant tumors (**FIG 2**).
- These tumors include primary bone tumors (eg, osteogenic sarcoma) or more commonly, metastatic spread from squamous cell cancer of the soft tissues of the head and neck (eg, floor of mouth or tongue).
- Osteoradionecrosis is a common complication of radiation therapy of the head and neck and in some cases results in late defects of the mandible. These patients present with nonhealing wounds or pathologic fractures of the mandible and in some cases, benefit from resection of the necrotic bone and reconstruction with free flaps.
- Benign lesions such as ameloblastoma, giant cell tumors, odontogenic mandibular cysts, and odontogenic tumors (ie, ameloblastoma) also require resection and reconstruction. These lesions do not metastasize but can be locally aggressive and have a high risk of recurrence if not resected with appropriate margins.
- Traumatic injuries, and less commonly infectious etiologies (eg, refractory

osteomyelitis), resulting in bone loss or complex lesions with nonunions also require osseous reconstruction in select cases.

- Congenital defects of the mandible in rare cases require free tissue transfer with bone flaps. More commonly, these defects are treated with bone grafting or distraction osteogenesis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and findings will depend mainly on the cause of disease process.
- For all patients, bone donor sites should be carefully assessed for blood supply, quality of soft tissues, and bone stock.
- Similarly, the anticipated defect in the mandible should be assessed for osseous and soft tissue needs and recipient vessels for microsurgery. Mouth opening, mastication, and swallowing should be examined.
- The quality and quantity of the teeth should be assessed and dental consultation should be obtained as needed.
- Dental rehabilitation (bone implants at the time of surgery or in a delayed fashion versus dentures) should be considered if feasible and discussed with the dental team.
- Medical comorbidities, prior treatments, planned treatments postoperatively, and prognosis should be assessed and noted whenever feasible.
- Patients with osteoradionecrosis or osteomyelitis may need to be optimized for treatment preoperatively using hyperbaric oxygen treatment, debridement, and antibiotic treatment as needed.

IMAGING

- Fine cut (1-mm-thick sections) CT scans of the mandible and fibula with 3D reconstruction is the best option for examining the bone and for planning of the reconstruction. MR imaging may also be useful in some cases to evaluate the surrounding soft tissues but is not useful for developing 3D bone models (**FIG 3**).^{1,2}
- The mandibular CT scan is usually performed as a noncontrast study because the primary need is to evaluate the bone anatomy and anticipated defects.

FIG 2 • Common causes of mandibular defects. **A.** Right mandibular osteoradionecrosis with surrounding infection. **B.** Squamous cell carcinoma of the right hemimandible. **C.** Left mandibular ameloblastoma. **D.** Treacher Collins syndrome with resorbing left mandibular rib graft.

FIG 3 • **A.** Three-dimensional model of the mandible derived from thin cut CT scans demonstrating area to be resected (*red bars*). **B.** CT angiogram of the lower extremity and fibula anatomy.

- Imaging of the fibula flap is typically done with a CT angiogram to evaluate the osseous anatomy as well as the vascular blood supply. The angiogram is used to evaluate the vascular anatomy of the lower extremity (three vessel runoff, abnormal vascular anatomy), and the perforator anatomy of the skin paddle. This imaging helps with planning the placement of the osteotomies and

skin paddles.

- Although standard models of the fibula are available and may be used for planning, in our hands, CT scans of the patient's own fibula is more accurate since because is some variability in the shape of the bone that may alter the angles needed for shaping of the fibula.

SURGICAL MANAGEMENT

Preoperative Planning

- The CT scans of the mandible and fibula are used for preoperative virtual surgical planning with the oncologic surgeons, dentists (if necessary), and the reconstructive team.
- It is important for the ablative surgeon to be involved in the planning session to accurately plan surgical margins. In cases where there is doubt about the surgical margins, two separate plans can be prepared. This approach enables intraoperative modification of the virtual surgical plan depending on anatomic or oncologic findings. Thus, a “narrow” margin resection plan may be created as the initial plan; however, if intraoperative findings dictate larger resection, then the backup “wider” resection plan can be executed instead. This approach creates two separate cutting guides for the head and neck and fibula harvest plans (**FIG 4A**).

FIG 4 • A. Virtual surgical planning and design of

mandibular (*left*) and fibula (*right*) cutting guides. **B.** Top-down plan for mandible reconstruction. Double barrel fibula flap reconstruction is planned with positioning of the mandibular segment along the upper border of the mandible to facilitate dental implant placement. **C.** Fibula cutting guide with predictive holes for placement of prebent plates and positioning of double barrel segment. **D.** Final placement of dental implants with double barrel fibula flap reconstruction.

- We used to be concerned only with the position of the bone reconstruction, now we plan from the top down. We start with the jaws in occlusion during the virtual meeting, then the noninvolved jaw is removed, and we plan the surgical cuts (**FIG 4B**).
- Finally, if dental implants are planned, we position them with the dental team at this point. In general, we try to place our implants under opposing teeth. If creating a bridge, then we evenly spread out the implants to equilibrate forces (**FIG 4C,D**).

Positioning

- The patient is positioned supine with the neck extended using a shoulder roll.
- A roll (bump) is affixed on the OR table to position the lower leg at a 90-degree angle at the knee (**FIG 5**). A hip roll may be needed to shift the patient slightly away from the surgeon and facilitate positioning of the lower leg.
- Bony prominences and soft tissues are padded appropriately.
- The OR table may be rotated to facilitate positioning of the surgical, anesthesia, and nursing teams.

Approach

- In most cases, the fibula flap is harvested simultaneously with the head and neck resection. This approach decreases the surgical time and improves outcomes. However, in some cases, this is not feasible (eg, complex reconstructions, or cases in which it is not clear if the tumor is resectable). In these cases, fibula flap harvest is performed after the resection is completed.

FIG 5 • Placement of the bump on the OR table to help position the fibula intraoperatively.

- In general, it is possible to use the fibula flap from either side (ie, the flap that is ipsilateral or contralateral to the anticipated mandibular defect).
- The ipsilateral fibula flap will position the flap vessels laterally in the neck by simplifying the microsurgical anastomosis. In addition, because the septum is under the bone (ie, posterior to the fibula) in this flap orientation, the skin paddle may be easily used for extraoral reconstruction. The skin paddle in an ipsilateral flap can also be placed intraorally; however, because the septum needs to go up and over the mandible, the amount of skin available for intraoral reconstruction is more limited.
- The contralateral fibula flap (in relation to the mandible defect area) places the flap vessels medially in the neck by facilitating crossing over to the contralateral neck if necessary. In addition, in this flap orientation, the septum is above the bone thus facilitating intraoral placement of the skin paddle.
- With the right planning, either leg can be utilized for most cases.

TECHNIQUES

■ Fibula Flap Harvest

Design

- The bone and posterior septum are marked and a Doppler is used to localize skin perforators in the middle and distal thirds of the bone.
 - The position of these skin perforators can be checked with the preoperative CT angiogram.
- The size and shape of the skin paddle is marked to plan for intra- or extraoral reconstruction.
- Orient the skin paddle to incorporate the signal and the area designed for coverage either intraorally or otherwise. This should be done carefully because the fibula skin paddle has limited mobility in relation to the bone.
- Although not necessary in all cases, we almost always design and harvest a skin paddle. This can be used as a backup in case additional soft tissues are resected or the quality of the remaining soft tissues is questionable. In addition, the skin paddle can be used for postoperative monitoring.
 - In some cases, the vascularized fascia and de-epithelized skin paddle may be used to augment soft tissue defects to improve contour or to cover the fixation hardware and decrease the potential for erosion/exposure.
- A tourniquet is applied to the upper thigh and padded with Webril or gauze. We usually use a sterile tourniquet that is applied once the patient is prepped and draped.
 - The tourniquet is set to a pressure that is about 100 mm Hg higher than the systolic blood pressure.
 - The leg is elevated and partially exsanguinated using an Esmarch bandage (personal preference) or without a full exsanguination.
- Generally, 2 hours of ischemia are well tolerated. If longer periods are needed for flap harvest, the circulation can be re-established for 20 to 30 minutes and the tourniquet can be reapplied.

Incisions and Flap Elevation

- The lateral approach to the fibula is used. The anterior skin incision is performed, and the fascia is incised. The skin is elevated off of the underlying musculature taking care to avoid injury to the superficial peroneal nerve.
- The peroneus longus and brevis muscles are cut while applying tension on the muscles leaving a 5-mm cuff of muscle on the anterior surface of the fibula. Care should be taken in the upper part of the leg to avoid injury to the anterior tibial vessels and tibial nerve.
- The intermuscular septum is then incised.

- The posterior skin incision is performed, and the skin and fascia are elevated off of the musculature.
 - The septum is identified and perforating vessels in the septum are preserved.
 - Branches to the soleus muscle are ligated.
- The fibula is carefully separated from the soleus muscle and the perforating branches from the peroneal artery/vein to the soleus muscle are identified and divided.
- The flexor hallucis longus muscle (FHL) is identified and divided.
 - The amount of FHL that is harvested with the flap can be modified depending on the reconstructive needs. In some cases, very little FHL is needed (eg, anterior defects) and therefore the FHL muscle is carefully dissected away from the fibula.
 - In other situations, vascularized muscle can be used to obliterate soft tissue defects (eg, posterior defects of the mandible or patients with osteomyelitis). In these cases, the majority of the FHL muscle is harvested with the flap.
- The fibula is then osteotomized inferiorly and superiorly using an oscillating electric saw, taking care to avoid injury to the tibioperoneal trunk proximally.
 - This can be done by passing a right angle from below the fibula while directly visualizing the vascular trunk.
 - A malleable retractor or army-navy type retractor can then be placed around the bone to avoid inadvertent injury to the vessels.
 - Leave about 6 cm of fibula bone proximally and distally, and take slightly more if needed but leaving less than 4 cm of bone proximally or distally, may result in instability and require screw fixation.
- Bone clamps placed distally are used to pull the muscle out, and the distal peroneal vessels are identified and ligated.
 - The posterior tibialis muscle is then carefully incised taking care to avoid injury to the peroneal vessels that run deep to the muscle.
- The peroneal vessels are then dissected away from the tibial nerve and posterior tibial vessels.
- At this point, the tourniquet is deflated, and hemostasis is ensured.

■ Mandibular Osteotomy

- The ablative surgeons perform their exposure of the mandible, and the custom mandible cutting guides are applied and fixed in place.
 - The resection is then performed using the cutting guides.
- Frozen section margins are evaluated if necessary.
- Recipient vessels in the neck are exposed. Commonly, we use branches of the external carotid artery (facial, lingual, superior thyroid) and branches of the internal or external jugular veins.

■ Fibula Flap Osteotomy

- Place the personalized fibula cutting guide to the preplanned location on the fibula and mark the area of the osteotomies and dental implants (if planned).
 - The cutting guide is attached to the fibula with two monocortical screws in each segment to avoid movement/rotation. This is very important, particularly if simultaneous dental implant placement is planned (**TECH FIG 1**).
- If dental implants are planned, clear a landing point on the fibula with a freer elevator or cautery through the periosteum below the implant drilling guide.
 - All the holes and implant positioning should have been meticulously planned in the online sessions and printed into the guide.
 - We place the implants before any osteotomies are made because precise orientation and positioning of the implants is critical for their long-term success.
- Once the dental portion of the procedure is completed, a subperiosteal dissection is performed at the area where the fibula osteotomy is planned to protect the pedicle.
- Wedge osteotomies are then performed using an oscillating saw. The osteotomies may be fixated at this point using miniplates.
 - Alternatively, the flap may be transferred to the head and neck area and the osteotomies fixated with a reconstructive bar.
- We prefer to do all of this preparatory work while the flap still attached to the vascular pedicle in situ in order to minimize flap ischemia time. For less complex defects, however, osteotomies can also be performed on the back table after pedicle ligation.

Insetting the Fibula Flap Into the Mandibular Defect

- The flap pedicle is divided and the flap is transferred to the head and neck area.

TECH FIG 1 • Positioning of the cutting guide on the fibula and placement of dental implants prior to fibula osteotomies.

TECH FIG 2 • Submental view of customized reconstruction plate and fixation of the fibula flap to the mandible.

- The pedicle vessels can be dissected in a subperiosteal manner to position the vessels optimally for microsurgical anastomosis.
 - Care should be taken to avoid devascularization of the fibula.
- In most cases, we use a prebent reconstructive plate that has been customized for the patient.
 - This plate is applied to the mandibular defect based on the cutting guide (**TECH FIG 2**).
 - The fibula is then inset into the defect and fixated to the plate. Minor burring of the bone may be necessary to achieve an optimal fit.
 - Monocortical screws are used on the fibula and each segment is usually fixated with two screws to prevent movement. We generally avoid bicortical screws since this may result in pedicle injury or weakening of the bone.
- If a prebent plate is not available, then a 2-mm-thick reconstructive plate can be bent to the defect (ideally prior to mandibular resection) or based on 3D model.
 - Guiding elastics may be needed in these cases to precisely fixate the mandible and ensure proper alignment of the teeth.
- If we are planning a double barrel segment to increase the vertical height of the mandible, we resect a 2-cm periosteal sleeve between bone segments to prevent kinking of the vascular pedicle.
- Inset the skin flap (usually the posterior or deep portions) prior to revascularization to stabilize the vascular pedicle because bleeding may obscure visualization of this closure.

■ Microsurgical Anastomosis and Flap Inset

- Microsurgical anastomosis is performed using a microscope or loupes, and reperfusion is monitored.
- The remainder of the flap skin paddle is performed and the flap is trimmed as needed. Meticulous intraoral closure is critical to avoid complications like salivary leaks and complex infections.
- Skin monitoring sutures are placed for postoperative evaluation using a Doppler. In cases where the flap is buried or no skin perforator is available, an implantable Doppler may be used.

■ Dental Implants

- If dental implants are placed at the time of reconstruction, we generally unroof and expose these implants 4 to 6 months postoperatively, when the bone has undergone appropriate osteosynthesis.³
- In the rare case of a benign tumor in which most or all of the mucosa is being spared, we can contemplate a single-stage reconstruction with fibula, placing the implant, then direct prosthesis placement.¹⁰
 - These cases require good soft tissue so that we can cover around the implant abutments and under the prosthesis to protect against salivary leakage. If we are not able to do this with well-vascularized mucosa or fascia, then prosthesis placement may not be possible and a well-vascularized skin paddle should be put in place.

PEARLS AND PITFALLS

Imaging timing

- When planning a resection, the preoperative CT scan should be obtained relatively close in time to the planning session and the surgery to avoid changes in the resection plan.

Planning session¹¹

- The tumor or disease process should be outlined by the modeling team and generous margins should be planned. It is best to do this with the ablative team involved during the online meeting so that they agree with this plan. If there is a question about margin safety and need for further intraoperative resection, an alternate guide can be made to accommodate for these potential changes.

Soft tissue planning

- Take into account your soft tissue needs when planning these procedures. Take as much skin as you need from your primary flap or choose alternative flaps if a complex resection is planned and there is a large intra- and extraoral soft tissue need. Do not leave yourself short of tissue.

Planning maneuvers to minimize soft tissue need

- In cases with significant tissue loss or lack of tissue flexibility such as in radiation injury, the bony reconstruction can be deprojected slightly to minimize strain on the overlying soft tissue and decrease the complexity of the reconstruction.

Plan approval

- Each team should evaluate the plan that is created by the engineers. This includes the ablative, dental, and reconstructive teams if dental prosthetic is planned.

Customized plates	■ As the reconstruction becomes more complex with multiple segments, predesigned plates can play an important role in obtaining very precise reconstruction results.
Primary implant consideration	■ Consider primary osteointegrated implants in benign cases and isolated malignant cases where the intraoral soft tissues are healthy and enable watertight closure around dental implants.
Bone size	■ Bone segments should remain at least 2 cm in length to maintain appropriate periosteal circulation.
Perforator location	■ Use the virtual planning to appropriately position your bone segments. Imaging can note 3D variations in the bone and perforator location, which can assist in the soft tissue design. Place skin where needed intra- or extraorally.
Fibula position and side decision	■ As a guideline, if both fibulas are available, when we have a need for an intraoral skin paddle and ipsilateral blood supply, we choose the contralateral fibula for orientation purposes. When skin is needed extraorally, with ipsilateral vessels, then the ipsilateral leg is planned. This arrangement can be adjusted based on the need of the situation. This is also the case with anterior defects, the location of the cutaneous defect and side of vascular supply will help determine which fibula will fit best.
Accuracy strategies	■ When using multiple segments or have critical positional requirements such as needed for primary implant placement, make intermediary splint devices to help confirm the position of the reconstruction as you advance through each step. Also, predictive hole guides and customized plating can help with this accuracy significantly.
Vessel dissection	■ Maximize peroneal vessel length as needed up to the attachment to the posterior tibial vessels.
Double barrel	■ When planning a double barrel segment, we find that a 2-cm (or greater if needed) periosteal sleeve allows for appropriate rotation.
Implant planning	■ Planning for implants should be performed from the top down. Need to plan the position based off of the maxillary dentition. If bone is not planned out appropriately, then implant position may also not be appropriate.
Implant placement	■ If placing primary implants, we place the guide and the implants first prior to performing the osteotomies. This helps to maintain accuracy.

POSTOPERATIVE CARE

- Postoperative care monitoring depends on the underlying health of the patient. In most cases, ICU observation is not necessary and may delay ambulation and tracheostomy decannulation.
- Head movement usually limited to less than 25 degrees first week postoperatively. The head is maintained in the neutral position and external compression of the vascular pedicle is avoided.
- Monitoring is preferred with physical assessment of the skin paddle color and pencil Doppler. The skin paddle may also be stuck with a needle and bleeding evaluated directly. In patients with implantable Dopplers, the skin paddle (if available) is still evaluated for color and refill. Monitoring protocol is in place with q1h flap checks for the first few days postoperatively and then decreasing to q2h and q4h thereafter.
- The ankle is splinted at the conclusion of the procedure in neutral position with a plaster or fiberglass splint.
 - Alternatively, a preordered walking type of ankle-foot orthotic (AFO) can be obtained so the patient can ambulate early in the postoperative period. Physical therapy consultation is useful in most cases to improve movement and stabilize early ambulation.
- If a skin graft is placed for the skin donor site, we usually use a VAC as a bolster for 5 days. Patients may ambulate with the VAC in place. Once the VAC is removed, ambulation is limited until the skin graft has completely taken.
- Compression wrapping with ACE bandage and elevation is usually needed for 1 to 2 months postoperatively.
- Feeding tubes are placed transnasally in the operating room and the position is confirmed radiologically. Tube feeds are usually started postoperative day one on and can be maintained until healing has occurred. Long-term tube feeds may require gastric tube placement.
- Swallowing function may be assessed if necessary in patient who have undergone floor of mouth resection. In these cases, speech/swallow evaluation may also be necessary.
- Once intraoral healing has been confirmed and the tracheostomy has been removed, oral feeds can be started and advanced as necessary.
- Most patients who undergo mandible reconstruction require tracheostomy. The timing of decannulation is dependent on the patients' recover. In most cases,

we downsize the tracheostomy by 3 to 4 days postoperatively once the intraoral and tongue swelling is decreased. Then from there advance to decannulation within another 1 to 2 days.

- Care must be taken to avoid tracheostomy ties to prevent compression of the pedicle. In these cases, tracheostomies are usually sutured or stapled into place.
- Most patients are discharged home by 7 to 14 days postoperatively.
- Some patients, depending on their preoperative condition, benefit from a short stay in a subacute rehabilitation center.

OUTCOMES

- Patients usually do very well postoperatively.⁴
 - By 6 to 8 weeks, ambulation is usually back to normal and the facial aesthetics are stabilized.
 - If chemotherapy or radiation is necessary postoperatively, this can usually be performed safely by 6 to 8 weeks postop.
- Oral function should be normalized by 2 to 4 weeks postoperatively especially if the tongue was left intact.
- Bone healing between the osteotomy sites should be well integrated by 3 to 4 months.
- If a patient is treated with radiation postoperatively, then dental implant placement requires careful consideration because the bone is at high risk of breakdown and implant failure.
- The reconstruction plates can be left in place unless there is hardware failure, exposure, pain, screw loosening, or palpability.
- Dental implants result in an excellent reconstruction (**FIG 6**).

COMPLICATIONS

- Typical complications include infections, bleeding, salivary leaks, malocclusion, pain, and nerve complications (sensory impairment, or more rarely, motor difficulties). Medical complications including pneumonia, aspiration, and cardiovascular morbidity may also occur. Donor site complications may include impaired healing, skin graft loss, pain, and neurovascular injury. Vascular complications from the donor site are rare but possible in patients with atherosclerotic disease.

FIG 6 • Postoperative view of the final reconstruction with dental implants in place.

- Long-term problems may include trismus, pain, and speech/swallowing problems. In addition, patients may have nonunion or implant-related complications.
- Airway risks are particularly worrisome in the early postoperative period especially if there is a large anterior or floor of mouth resection.

Mandible Reconstruction With Fibula Flap With Templates

CHAPTER 11

Eric G. Halvorson

DEFINITION

- Mandible reconstruction is most commonly indicated following tumor extirpation, although it is also indicated for posttraumatic defects of the mandible. Less common indications include osteoradionecrosis and infection.
- The fibula flap remains the standard for microvascular mandible reconstruction.
- Although many descriptions of surgical technique exist, the closing wedge osteotomy remains a “black box” for learners.
 - In this chapter, a simple and reliable technique to create anatomic wedge osteotomies is presented, using preoperative templates based on the patient’s native anatomy.

ANATOMY

- The anatomy relevant to fibula flap harvest is presented in Chapter 10 of this section, as well as techniques for neomandible creation using CAD/CAM osteotomy jigs.
- This chapter focuses exclusively on how to create a neomandible using traditional templates and closing wedge osteotomies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Risk factors for wound healing complications should be assessed, including radiation exposure, smoking, diabetes, steroid use, poor nutrition, and obesity.
- Prior neck dissection can make reoperation and recipient vessel exposure difficult. A history of lower extremity trauma, surgery, or peripheral vascular

disease may preclude use of the fibula flap.

- The oral cavity is examined and the expected defect analyzed for quantity of bone and lining required.
 - Patients with poor dentition who will require adjuvant radiotherapy may benefit from dental extraction.
 - Occlusion is assessed and carefully noted, as one goal of surgery is to maintain native occlusion.
- Distal lower extremity pulses and skin texture are examined.
 - Patients with potential vascular disease should undergo preoperative imaging to evaluate three-vessel runoff.
 - Patients with taut or thin skin will likely require a split-thickness skin graft for donor-site closure.

IMAGING

- Craniofacial CT scans are performed to assess the extent of disease (tumor, traumatic defect, osteoradionecrosis, infection).
 - Three-dimensional renderings are helpful but not necessary.
- Lower extremity angiography is commonly performed (CTA or MRA) to assess three-vessel runoff. If these studies are inadequate, conventional angiography is performed.
 - Patients must have at least a patent anterior tibial or posterior tibial artery (in addition to the blood supply of the flap derived from the peroneal artery) to be candidates for fibula flap harvest.

SURGICAL MANAGEMENT

Preoperative Planning

- Excellent communication between the extirpative and reconstructive surgeons is necessary to coordinate perioperative planning, including staging of disease, imaging, labs, and clearance for surgery.
- In delayed reconstruction, eg, in patients treated for traumatic defects, it is helpful to have two surgeons involved (one to recreate the defect and expose recipient vessels and the other to elevate the flap). However, this is not an absolute requirement.
- A secure airway is required in the perioperative period, as flap swelling, abnormal deglutition, and secretions can compromise the airway. In addition, emergent reintubation may compromise microsurgical reconstruction and

disrupt the repair. As a result, a tracheostomy is almost always indicated until adequate healing has occurred to allow decannulation.

- Adequate nutrition is important in the perioperative period.
 - A flexible nasogastric or nasoduodenal tube is often placed at the end of surgery for early initiation of tube feedings.
 - If patients are malnourished prior to surgery, a percutaneous endoscopic gastrostomy tube may be considered.

Positioning

- Patients are placed in supine position with a bump under the shoulders and the neck extended.
- A folded towel or blanket is placed under the hip to facilitate internal rotation when the hip and knee are flexed.
- A padded roll or IV bag is secured to the table so the foot can rest on it with the hip and knee flexed (and internally rotated). This facilitates exposure and dissection.
- The heels and lower extremity are padded to avoid pressure sores during these long procedures.
- The entire lower extremity is prepped and a sterile tourniquet is used so the thigh can later be used as a donor site for a split-thickness skin graft if needed.

Approach

- If the defect is truly central, and both necks are available for recipient vessels, then either extremity can be utilized to harvest a fibula flap.
 - The left is preferable as most patients use their right leg for driving, etc., but angiographic findings may also dictate which side to use.
- An ipsilateral flap (with respect to the location of the defect in the jaw) is typically used. This approach places the septum carrying the cutaneous vessel/s externally and inferiorly.
 - This allows the septum and skin to be brought over the hardware and into the oral cavity for standard gingiva/floor of mouth defects.
 - In addition, using the ipsilateral flap places the pedicle vessels laterally on the fibula flap thus localizing the vessels in optimal position for microsurgical anastomosis to the neck vessels.
- A contralateral flap will place the septum and skin island internally and superiorly, which may be preferable when there is a large intraoral defect that

extends beyond the gingiva/floor of mouth.

- A two-team approach is preferable to reduce operative time.
- The flap can be elevated during extirpation, provided there is good communication between the two operative teams and an accurate estimate of the defect is made.
- It is prudent to take more flap than you think you might need.
- The neomandible can be created in situ on the leg, further reducing both operative and ischemic time.

TECHNIQUES

■ Maintaining Native Condyle Position and Occlusion

- Mandibular discontinuity leads to abnormal condylar positioning and malocclusion, as the muscles of mastication contract each segment unopposed. Significant distortion of native condylar positioning when re-establishing mandibular continuity can lead to malocclusion and/or abnormal movement when chewing.
- If the disease process has not distorted the outer border of the mandible, *prior to resection* a reconstruction bar can be appropriately bent and secured to it using two screws on the nonpathologic side of each planned extirpative osteotomy.
 - Following resection, the bar is replaced and the fibula flap can usually be secured to it, provided it maintains occlusion and there are not large gaps (greater than 3 mm) between the bar and fibula.
 - Locking screws are required when gaps exist, to prevent distortion of the bony segments and gaps between bone and bone (worse than gaps between bone and hardware).
- If necessary, a new bar can be appropriately bent (using osteotomy templates) and secured, although it may be necessary to place the patient in temporary mandibulomaxillary fixation (MMF) to maintain occlusion during the revised osteosynthesis.
- If the disease process has grossly distorted the external surface of the mandible, placing the patient in temporary MMF after resection will maintain

condylar positioning and proper occlusion for bony inset of the fibula flap.

- For edentulous patients, a reconstruction bar can be bent around the tumor and secured to the normal segments of the bone as above. This bar can be replaced with a new bar that is bent using the osteotomy templates. In this case, the initial bar should be secured to the normal segments using holes that are not near the cortex designated for final osteosynthesis.
- The author's preference is to avoid postoperative MMF if the teeth easily come into good occlusion following final flap inset.
 - It is unlikely that significant malocclusion following osteosynthesis of the neomandible will be corrected with MMF. Adjusting how the bony segments are secured to the hardware may be necessary to optimize native occlusion.
 - For edentulous patients, occlusion is not a factor and anatomic inset is not as critical.

■ Creating Anatomic Templates

- The lowest axial cut of the mandible on preoperative CT is printed and the outer surface traced and cut to create linear segments separated by distinct angles (**TECH FIG 1A,B**).
- Mandibular angle templates are based on the appropriate sagittal image.
 - Although it is possible to print 1:1 ("life size") images of the CT, the osteotomy angles are the same regardless of magnification.
- A template is created for each osteotomy by tracing the printed CT onto a plastic sheet (eg, a sterile plastic bowl) that is sterilized with Betadine or chlorhexidine (**TECH FIG 1C,D**).
- It is critical to draw the inner (lingual) lines parallel to the outer (buccal) lines and the exact same distance from them (ideally 1 cm).
 - The junction of these lines forms a point that is critical in subsequent steps (**TECH FIG 1E**).

TECH FIG 1 • The lowest axial cut of the mandible on preoperative CT is printed **(A)** and the outer surface traced **(B)** and cut to create linear segments separated by distinct angles. **C,D**. A template is created for each osteotomy by tracing the printed CT onto a plastic sheet (eg, a sterile plastic bowl) that is sterilized with betadine or chlorhexidine. **E**. It is important to draw the inner (lingual) lines parallel to the outer (buccal) lines and the exact same distance from them (ideally 1 cm). The junction of these lines forms a point that is critical in subsequent steps.

■ Fibula Flap Elevation

- Doppler interrogation along the septum between the lateral and superficial posterior compartments (2 cm posterior to the fibula) at the junction of the middle and distal thirds of the lower extremity should reveal several signals.
 - An appropriate skin paddle is designed centered on the septum and marked Doppler signals.
 - The incision should extend proximal to the skin island to facilitate exposure of the tibioperoneal trunk.
- The leg is elevated and exsanguinated with manual compression or an

Esmarch bandage. The sterile thigh tourniquet is inflated to 250 to 350 mm Hg.

- The anterior incision is made and dissection is carried down to the fascia with cautery.
 - Is it prudent to bevel out several centimeters and then make the fascial incision, to ensure that the septum is incorporated into the flap.
- During the anterior dissection, it is important to try and avoid injury to the superficial peroneal nerve.
- Following the fascial incision, Allis clamps are placed on the fascial edges, and the flap is elevated off the underlying peroneus longus using blunt dissection and cautery.
 - The septum will be present on the posterior surface of the peroneus longus, and a septocutaneous branch of the peroneal vessel should be visualized.
- The lateral compartment musculature is then pulled away from the fibula and elevated off the bone, leaving a small (2 mm) cuff of muscle on the bone to avoid thermal injury to the periosteum.
 - The septum between the anterior and lateral compartments will be encountered and should be incised carefully to avoid injury to the anterior tibial vessel and deep peroneal nerve.
- Retractors are placed to elevate the anterior tibial vessel and deep peroneal nerve, and the anterior compartment musculature is elevated off the fibula as above.
 - The interosseous membrane is next encountered and is incised along its length by preserving roughly 6 cm of fibula proximally and distally.
- The critical structures to avoid are the peroneal vessels and nerve proximally and the ankle syndesmosis distally.
 - Preserving 6 cm proximally and distally typically accomplishes this, but dissection should follow individual anatomic landmarks and not static measurements.
- The anterior incision is temporarily stapled and the posterior incision is made. As above, beveling out several centimeters at the level of the fascia will ensure the septocutaneous branch of the peroneal vessel is preserved.
- It is prudent to avoid injury to the sural nerve during the superficial posterior dissection.
- The fascia is incised and grasped with Allis clamps, and the skin paddle is elevated off the underlying soleus muscle. This should isolate the skin paddle

on the septum.

- The attachments of the soleus muscle to the fibula are taken down with blunt dissection and cautery, exposing a potential space between the soleus muscle and flexor hallucis.
 - Multiple large branches of the peroneal pedicle to the soleus muscle are typically observed proximally and ligated.
- A right-angled clamp is placed around the fibula proximally and distally, taking great care not to injure the peroneal neurovascular bundle proximally.
 - The clamp is used to bluntly dissect a space that will accept an Army-Navy retractor, which is then used to protect the soft tissues as the proximal and distal osteotomies are performed with a sagittal saw.
- The distal bone is gently grasped with a bone clamp and pulled out of the wound, which should expose the distal peroneal pedicle to be ligated.
 - The epimysium of the flexor hallucis is incised via the posterior approach, which allows easier retraction of the flap.
- The author's preference is to transect the flexor hallucis distally and include it with the flap.
 - If the muscle is left behind, it is avascular and has no origin. This can result in a hammertoe deformity due to contracture.
 - Most patients do not notice its absence, except young athletes or dancers.
 - With an ipsilateral flap, the muscle will hang below the neomandible, buttressing the floor of mouth repair and filling in the soft tissue defect from lymphadenectomy. If the cutaneous pedicle is injured, the muscle can serve to close floor of mouth and other defects.
- While retracting the distal flap out of the wound, the tibialis posterior will be visible from the anterior approach, with its characteristic chevron fiber orientation.
 - This muscle is divided from the fibula leaving a 1-cm cuff to avoid injury to the flap.
 - Posterior to this muscle lies the septum between the superficial and deep posterior compartments. This septum is carefully incised, to avoid injury to the peroneal pedicle immediately below.
- The flap is elevated from distal to proximal, where the peroneal vessels are identified and dissected to their origin off the tibioperoneal trunk. The veins often have multiple branches, necessitating careful dissection.
- The tourniquet is let down, and hemostasis is achieved.

- During flap inset, it is helpful to have a second surgeon perform donor-site closure.
 - The wound is irrigated and hemostasis achieved.
 - A drain is placed and the skin is closed with interrupted deep dermal and running subcuticular absorbable suture.
 - It is critical to avoid compartment syndrome and therefore surgeons should have a low threshold to place a split-thickness autograft if primary closure is too tight.
 - Sterile dressings and a well-padded posterior splint is applied.
 - Patients may get out of bed to a chair with their leg elevated but do not ambulate until postoperative day 5.
-

■ Marking the Osteotomy Sites

- The length of each segment is estimated by measurement of the defect and/or specimen, and osteotomy sites are marked on the fibula (**TECH FIG 2A,B**).
 - It is possible to use the template in determining segment length, but only if it is printed out as a 1:1 image and not overly affected by the disease process (in which case the contralateral mandible may be used as a mirror image).

TECH FIG 2 • A,B. The length of each segment is estimated by measurement of the defect and/or specimen and osteotomy sites are marked on the fibula. **C–F.** The outer point of the template is lined up with the point of osteotomy and one edge of the template is held parallel to the anterior surface of the fibula. The point formed by the junction of the two inner (lingual) borders of the template is used to mark one side of the closing wedge osteotomy, then the other edge of the template is held parallel to the outer surface of the fibula and the marking for the closing wedge is finalized. **G–I.** It is important to recognize that the inner angle of the template is used, and not the outer borders; otherwise, an inverse angle osteotomy will be formed.

- The outer point of the template is lined up with the point of osteotomy and

one edge of the template is held parallel to the anterior surface of the fibula.

- The point formed by the junction of the two inner (lingual) borders of the template is used to mark one side of the closing wedge osteotomy, then the other edge of the template is held parallel to the outer surface of the fibula, and the marking for the closing wedge is finalized (**TECH FIG 2C–E**).
 - It is important to recognize that this inner angle is used, and not the outer borders of the template, or else an inverse osteotomy will be formed (**TECH FIG 2F–I**).
 - It is critical not to design an osteotomy where the septocutaneous branch of the peroneal vessel emerges.
 - This can be avoided by moving the planned osteotomy 1 cm to either side of the vessel to avoid injury during osteotomy.
-

■ Closing Wedge Osteotomies

- Closing wedge osteotomies are then performed using a reciprocating pneumatic or electric saw, protecting the peroneal vascular pedicle by passing a snap under the bone to place it between the periosteum and vascular pedicle.
 - The osteotomies created should match the template with a high degree of accuracy (**TECH FIG 3A–C**).
- Reconstruction of the mandibular angle can be performed in the same manner (**TECH FIG 3D–G**).
- Osteotomies can be performed with the raised fibula flap in situ by using the measurements and templates (**TECH FIG 3H**).
- Miniplates or reconstruction bars can be bent using the template for even more accuracy in constructing the neomandible (**TECH FIG 3I**).¹
 - Although it is potentially more accurate to use miniplates, it is often easier and faster to use a reconstruction bar. This typically yields a similar result. However, in the event of an infection, it is far easier to remove miniplates than a reconstruction bar.
 - The important thing is that occlusion and aesthetics are optimized.
- For three or more osteotomies, a virtually planned osteotomy jig should be considered to create three-dimensional osteotomies.
- Osteotomies can be performed in situ on the leg (to reduce operative and ischemic time) or during flap inset.

TECH FIG 3 • A–C. Closing wedge osteotomies are performed using a reciprocating saw, protecting the peroneal vessels by passing a snap under the bone to place it between the periosteum and vascular pedicle. The osteotomies created should match the template with a high degree of accuracy. **D–G.** Reconstruction of the mandibular angle can be performed using a closing wedge osteotomy on the outer surface of the fibula in the same manner as described above. **H.** Osteotomies can be performed with the raised fibula flap in situ utilizing the measurements and templates. **I.** Miniplates or reconstruction bars can be bent using the template to optimize accuracy in constructing the neomandible.

- To facilitate inset of the skin island, the septum can be incised if needed, if the septocutaneous branch of the peroneal vessel is preserved and not overly twisted.
- The skin island is appropriately trimmed and inset using interrupted

absorbable suture, and the remainder of the surgical wounds are closed over drains after irrigation.

- To test intraoral closure, gauze can be placed in the neck under the closure and the mouth irrigated with dilute methylene blue solution.
- If the gauze has blue staining, then the closure is not tight enough.

PEARLS AND PITFALLS

Preoperative planning

- Review the patient's exam findings and imaging with the extirpative surgeon to anticipate the location and size of the defect.
- Careful physical examination is more important than imaging, which may include lower extremity angiography.
- Consider placing a reconstruction bar prior to resection, to maintain native condylar positioning and dental occlusion.

Approach

- An ipsilateral flap is typically used, which optimizes inset for the microsurgical anastomosis to the ipsilateral neck vessels and closure of the floor of mouth and gingival defects.
- A two-team approach is helpful for both immediate and delayed reconstructions to reduce operative time.

Positioning

- A hip bump (eg, folded towel) and secured/padded foot rest allow the donor extremity to be positioned with hip/knee flexion and internal hip rotation, thus facilitating exposure.

Creating a template

- The lowest axial cut of the mandible on CT is printed and the outer surface traced and cut to create linear segments separated by distinct angles. This forms the basis for plastic templates specific to each osteotomy.

Closing wedge osteotomies

- Templates are used to mark each closing wedge osteotomy. Use the inner angle of the template, not the outer surface.
- Protect the peroneal pedicle with a snap during each osteotomy.

POSTOPERATIVE CARE

- Patients are admitted to an intensive care unit for ventilator management and hourly flap checks.
- The author's preference is to use clinical exam to monitor most flaps, reserving internal Dopplers or tissue oximeters for difficult cases where the

pretest probability of flap failure is higher, thus increasing the positive predictive value of the monitoring device.

- For buried flaps, an internal Doppler is usually used if the microanastomosis proved difficult.
- Tube feeds are initiated on postoperative day 1 or 2, and oral care with chlorhexidine solution is provided every 8 hours.
 - The head of bed is maintained in an elevated position, with no pillows or circumferential neck ties to prevent kinking or compression of the pedicle.
 - The donor leg is kept elevated on pillows.
- Antibiotics are typically discontinued after 24 hours. However, longer course of treatments can be considered in high-risk patients (eg, those with a preoperative history of radiation, heavy smokers, compromised skin, or preoperative infection).
 - Subcutaneous heparin or enoxaparin is given preoperatively and postoperatively until discharge.
- Drains are removed when output is less than 30 mL/d.
- A formal swallow study is rarely performed unless a leak is suspected. A bedside swallow evaluation is performed to guide diet advancement.

OUTCOMES

- This technique is a very simple way to create anatomic closing wedge osteotomies. For most patients requiring one or two osteotomies, this technique is successful in restoring preoperative occlusion and facial aesthetics (**FIG 1**).
- For patients without good dentition, this technique reliably restores condylar positioning. For patients requiring three or more osteotomies, or osteotomies in multiple planes (eg, subtotal mandibulectomy), a more accurate reconstruction is likely to be achieved using a custom three-dimensional osteotomy guide created preoperatively based on the patient's CT scan.^{2,3}

FIG 1 • This technique is a simple way to create anatomic closing wedge osteotomies that restore preoperative occlusion and facial aesthetics.

COMPLICATIONS

- Complications are similar to other head and neck microvascular reconstruction cases and can include flap necrosis, orocutaneous fistula, wound dehiscence, and functional problems with speech and swallowing (that usually improve with time and therapy).
- Malunion or nonunion of the bony segments is rare, although late hardware infection can occur. This usually manifests as an intraoral wound with hardware exposure or an external sinus tract with granulation tissue.
- Donor-site complications include wound dehiscence, exposure of peroneus longus tendon, hammertoe, skin graft loss (if used), compartment syndrome, and functional problems with gait.
- Young patients tolerate fibula harvest well. Older patients may require use of a walker or cane, at least initially.
- It is common for patients to have pain and swelling late in the day, which persists for months after surgery.

12 Mandible Reconstruction With Scapula Flap

CHAPTER

Mouchammed Agko and Hung-Chi Chen

DEFINITION

- Reconstruction of the mandible requires bone to replace osseous defects and soft tissues to reconstruct the floor of mouth, tongue, soft palate, and/or external skin. This combined soft tissue and osseous reconstructive needs, in combination with vascular anatomy and other patient factors, determine the optimal donor site. In specific circumstances, the subscapular system of flaps can be employed for this purpose.
- The subscapular vascular system is one of the most versatile and reliable donor sites with consistent anatomy that can provide a multitude of skin, fascia, muscle, and osseous flaps combinations.
- Saijo and dos Santos laid the anatomic foundations for the scapular flap leading to the first successful microsurgical transfer by dos Santos, Gilbert, and Teot.^{1–3} Nassif subsequently described the parascapular flap.⁴
- In 1981, Teot et al. reported use of an osseous scapular flap based on the circumflex scapular artery (CSA).⁵ Later, Swartz et al. popularized the use of the osteocutaneous scapular flap for mandibular reconstruction.⁶
- Historically, it is interesting to note that although Ignio Tansini is credited for the first description of the latissimus dorsi flap, his initial depictions of the flap have been actually determined to be consistent with that of a parascapular flap.

ANATOMY

- The subscapular artery (SSA) arises at the distal border of the subscapularis muscle from the third portion of the axillary artery.
 - It measures 2 to 4 mm in diameter and courses for 2 to 3 cm prior to dividing into the CSA and thoracodorsal artery (TDA).

- The CSA, which is 1.5 to 3.5 mm in diameter, courses for 3 to 4 cm before it gives off the branches to the lateral border of the scapula.
- It enters the triangular space (omotricipital triangle) that is formed by divergence of the teres muscles from the lateral scapula (teres minor superiorly, teres major inferiorly) and the long head of the triceps laterally.
- At this level, it sends branches to the subscapularis muscle and numerous musculoperiosteal branches to the lateral border of the scapula.
- Subsequently, it gives off branches to the infraspinatus and teres muscles.
- It is the musculoperiosteal branches between the anterior subscapularis muscle and the posterior teres muscles that provide the vascularization of the upper two-thirds of the lateral scapula and have to be preserved during harvest of the lateral osseous flap.
- The distance from the axillary artery to these branches (effectively the pedicle length of the flap) is 6 to 8 cm.
- After emerging through the triangular space, the CSA is encased in the dorsal thoracic fascia.
- An areolar space separates this from the underlying deep muscle fascia.
- The CSA courses caudally for 2 to 3 cm before it divides into its terminal branches: ascending, transverse, descending, and anterior.
- Although all these can serve as the source for axial flaps overlying the specific branch, the two most commonly used are the scapular and parascapular flaps based on the main transverse and descending branches, respectively (**FIG 1**).

FIG 1 • The vascular supply of the scapular/parascapular skin paddles and the lateral edge/tip of the scapula osseous flaps are shown. After giving off musculoperiosteal branches to the lateral border of the scapula (lateral osseous flap), the circumflex scapular artery emerges through the triangular space and divides into its terminal branches. The transverse and descending branches supply the scapular and parascapular skin paddles, respectively. The tip of the scapula receives its blood supply from the angular artery that is a branch of the thoracodorsal artery itself or its serratus anterior branch.

- The circumflex scapular system has two veins of disparate size that coalesce before joining the single vein of the thoracodorsal system to form the

subscapular vein (SSV) (2.5–4 mm in diameter).

■ Anatomic variations:

- Double CSA (8%–14%)
- Double circumflex scapular vein (CSV) (14%)
- CSA originating separately from the axillary artery (4%–8%)
- CSV originating separately from the axillary vein (12%)
- Descending branch of the CSA (parascapular flap pedicle) coursing anterior to the teres major muscle (TM) and emerging between the inferior border of the teres minor muscle (Tm) and the superior border of the latissimus dorsi muscle (7 of 30 cases)
- SSA and thoracoacromial arteries sharing a common origin from the axillary artery (2–47 cases)

PATIENT HISTORY AND PHYSICAL FINDINGS

- The shoulder and axillary area is carefully examined. Range of motion of the shoulder joint and strength of the parascapular muscles are determined.
- Previous injuries and surgical interventions in the vicinity are scrutinized to assess potential damage to the vascular structures precluding safe harvest.
- Although scars involving just the skin do not preclude harvesting the cutaneous portion of the flap, deeper scars (eg, previous thoracotomy incision, previous axillary lymph node dissection) may have injured the pedicle or the flap.
- Special attention is paid to identify spinal accessory nerve injury by examining trapezius muscle bulk and function. Further compromise of parascapular muscles may exacerbate winging of the scapula.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- No preoperative studies are required.
- In cases of previous injury or surgery, angiography (conventional, computed tomography, or magnetic resonance) can be employed to confirm intact vascular anatomy.
- Theoretically, x-rays of the scapula or computerized tomography with 3D reconstruction could be used for preoperative planning.
- For the purposes of photographic documentation, preoperative photos of the donor site and shoulder function are obtained.

SURGICAL MANAGEMENT

- The available reconstructive options for mandibular defects are as follows:
 - Osteocutaneous fibula flap
 - Vascularized iliac crest flap
 - Osteocutaneous scapula flap
 - Osteocutaneous radial forearm flap
 - Vascularized rib with blood supply from the latissimus dorsi muscle
 - Vascularized medial femoral condyle corticoperiosteal flap for short defects of the mandible
 - Reconstruction plate covered with pedicle or free myocutaneous flap
 - Delayed repair with nonvascularized bone graft
- Anterior, sagittal, or hemimandibular defects can be restored with the osteocutaneous scapula flap.
- Specific indications for the use of the osteocutaneous scapular flaps in mandibular reconstruction include the following:
 - Composite defects of the mandible with large soft tissue requirements for intraoral lining, external coverage, and/or soft tissue augmentation.
 - The soft tissue defect is not directly adjacent to the osseous defect and relative independence is required between the bone and soft tissue component for optimum inset.
 - Fibula is not available due to vascular disease, aberrant anatomy, injury, or previous harvest.
 - Patient wants to avoid the morbidity of vascularized iliac crest harvest.
- Medical status prohibiting lengthy procedures under general anesthesia would preclude the use of this flap.
- Relative contraindications include the following:
 - Osseous defect larger than 14 cm in men or 10 cm in women
 - Need for multiple osteotomies that could endanger viability of the osseous flap
 - Pre-existing shoulder disorders limiting range of motion and periscapular muscle strength
 - Damage to the vascular pedicle due to injury or procedure (eg, lymphadenectomy)
 - Skin of the back too thick (obese patients)
- There are numerous advantages of this flap compared to other options for mandibular reconstruction.
 - The hairless nature of the scapular skin flap closely resembling the texture

and sometimes color of the facial skin.

- The vascular pedicle can be dissected to the appropriate length and diameter to match the recipient vessels.
- Additional flaps can be carried on a single arterial and venous anastomosis except in cases of anatomical variations.
- The soft tissue elements can be spatially oriented independently of each other or the bone enabling coverage of complex composite defects.
- Primary closure of large skin flaps is possible providing more skin than other osteocutaneous flaps.
- Limited morbidity with minimal loss of shoulder function if no preoperative limitation exists.
- The vascular pedicle is reliable even in patients with diabetes or arteriosclerosis.
- Scapular osteocutaneous flaps also have some limitations.
 - Some authors have described flap harvest in a modified semilateral position to avoid redraping. However, most surgeons prefer to reposition the patient before and after flap harvest.
 - Two-team approach is not possible. Mandibular resection/recipient site preparation has to be completed prior to proceeding with the flap harvest.
 - Revascularization of the flap can only be performed after donor-site closure.
 - If undue tension is present at closure, the donor-site scar may be widened. However, patients rarely complain as the scar is not easily visible to them.
 - If skin grafting becomes necessary, this is an inherently unfavorable site.
 - Dissection of the CSA pedicle through the triangular space can be tedious and time-consuming.
 - Because the sensory branches from the 3rd to 5th intercostal nerves are divided during elevation of the flap, primary sensory innervation is not possible. However, when transferred to the head and neck region, the flap may regain satisfactory sensation without nerve repair through spontaneous regeneration from the tissue bed.
 - Bone stock may be limited in women precluding dental rehabilitation.

Preoperative Planning

- For preoperative marking and flap design, the patient is seated or stands comfortably with the arms resting at the sides.
- The borders of the scapula and its spine are marked.
- The triangular space is identified by palpating the lateral border of the scapula

at 2/5th of the distance between the center of the spine and the inferior angle of the scapula.

- The posterior axillary fold formed by the teres major (TM) is pinched between the thumb and the remaining fingers to identify the upper border of the muscle.
- The emergence point of the CSA from the triangular space can be located at area where the upper border of the TM meets the lateral border of the scapula.
 - A pencil Doppler can confirm the location of the CSA and the course of its branches.
- Scapular fasciocutaneous flap
 - The axis of the scapular flap is a line parallel to the spine of the scapula extending from the emergence point of the CSA to the posterior midline.
 - The flap itself is marked from the posterior axillary line to the posterior midline in a lenticular fashion with the medial end extending over the triangular space. The design is limited superiorly by the spine of the scapula and inferiorly by the inferior angle.
 - An additional 2 cm passing across the midline can be included as an extension based on random perfusion.
 - Usual flap dimensions allowing primary closure are 20 cm × 10 cm, with the length ranging from 6 to 25 cm and the width from 4 to 16 cm.
- Medial osseous flap
 - The scapular fasciocutaneous flap can carry an osseous segment from the medial border of the scapula (10–12 cm × 3 cm × 0.71–1.5 cm) through its fascial attachments to the bone.
- Parascapular fasciocutaneous flap
 - The axis of the flap corresponds to the lateral border of the scapula when the arm is in adduction.
 - The flap is marked from the posterior axillary crease superiorly and can extend to the 12th rib or midway between the inferior angle of the scapula and posterior superior iliac spine.
 - The width that would allow primary closure is confirmed by pinching the skin and subcutaneous tissue.
 - Usual flap dimensions allowing primary closure are 24 cm × 12 cm, with the length ranging from 6 to 32 cm and the width from 8 to 20 cm.
- Lateral osseous flap
 - The length of the lateral scapular bone that can be reliably elevated on the periosteal branches of the CSA depends on number of planned osteotomies.

- Usually up to 10 cm in women and 14 cm in men can be harvested, when one proximal osteotomy is planned.
- The bone can be up to 3 cm wide with variable thickness (1.5–3 cm) along the length of the flap.

FIG 2 • Bone flaps that can be harvested. **A.** Lateral osseous flap based on the periosteal branches of the circumflex scapular artery (CSA). **B.** Extended lateral osseous flap including the tip of the scapula where both the periosteal branches of the CSA and the angular artery are preserved. **C.** Tip of the scapula osseous flap based on the angular artery only.

- If more and/or distal osteotomies or longer bone is needed, the scapular tip (an additional 3 to 4 cm of bone) can be safely and simultaneously harvested based on the angular artery. Alternatively, the tip of scapula can be harvested as a separate vascularized bone segment (**FIG 2**).⁷
- The angular artery branches off the TDA or the serratus branch and travels on top of the serratus muscle beneath the TM.
- Because of the dedicated periosteal branches from the CSA, the lateral osseous flap is not dependent on the overlying skin for its vascular supply. Therefore, depending on the soft tissue defect, it can be elevated with a scapular or parascapular fasciocutaneous flap, or a combination of them (either combined in an L-shaped bilobed configuration or as separate skin paddles).

Positioning

- Although prone and modified lateral decubitus positioning has been suggested, the lateral decubitus position with the arm fully prepped in the operative field allows optimal access (**FIG 3**).

FIG 3 • The patient has been placed in right lateral decubitus position with the left arm abducted at 90 degrees. The scapular and parascapular skin paddles have been delineated in *blue*. The subscapular artery (SSA) is shown branching into the thoracodorsal (TDA) and circumflex scapular arteries (CSA). The CSA is shown emerging through the triangular space bound superiorly by the long head of the triceps (*TriL*), medially by the teres minor (*Tm*), and laterally by the teres major (*TM*). After giving musculoperiosteal branches to the lateral osseous flap (marked in *light green*), the CSA gives off a descending branch coursing caudally and a transverse branch coursing medially that supply the parascapular and scapular skin paddles, respectively. The outline of the latissimus muscle is also shown in *black*.

- During harvest of the skin paddle and bone, the arm is best kept in abduction for easy identification of the teres muscles.
- During harvest of the pedicle at the depths of the triangular space and exposure of the subscapular pedicle in the axilla, manipulation of the arm will allow easy exposure.
- An axillary roll and appropriate padding of pressure points are important to prevent brachial plexus injury and decubitus ulcer, respectively.

Approach

- Two different approaches exist for the harvest of the skin component of the flap, whether it is a scapular or parascapular one.
- In the medial approach, the skin paddle is elevated peripherally prior to dissection of the CSA.
- On the contrary, with the lateral approach, the pedicle is identified first through a limited incision followed by dissection of the skin island.

TECHNIQUES

Video p3-c012

■ Preparation of Recipient Site

- Prior to flap harvest, the recipient site should be examined to determine location, configuration, and size of the different components of the defect.

- The viability of remaining tissues should be assessed. If necessary, any tissue of questionable viability should be trimmed further.
- Recipient vessels should be exposed and prepared for expeditious revascularization after closure of the donor site and repositioning of the patient.
- After careful assessment of the defect and the recipient vessels, the following decisions on the specific flap design can be made: length of the osseous component, osteotomy sites and number, number and size of skin paddles, additional muscle flaps, optimal pedicle length, and inset of the flap.
- The axillary hair is clipped.
- The ipsilateral arm is fully prepped and included in the operative field as is the shoulder, axilla, and lateral torso from sternum and umbilicus anteriorly to spine posteriorly.
- The ipsilateral thigh should be prepared separately for possible skin graft harvest.

■ Skin Flap Harvest

- The skin flap can be harvested through either a medial or a lateral approach.

Medial Approach (Retrograde, Distal to Proximal)

- The course of the terminal branches of the CSA, transverse or descending, can be reliably estimated using anatomic landmarks and confirmed with a Doppler.
- The skin flap design is centered over this vascular axis by marking the triangular space and using a pencil Doppler to map out the vessel (see **FIG 3**).
- At the distal end of the flap, an incision is made through the skin down to, but not including, the deep muscle fascia (**TECH FIG 1A**).
- The dissection proceeds expeditiously in an areolar plane between the deep thoracic fascia, which carries the pedicle, and the underlying deep muscle fascia. Dissection over the latissimus muscle is done rapidly as the skin perforator in this area is in the flap (**TECH FIG 1B**).
- The skin incisions are extended proximally on both sides of the pedicle that is clearly visualized on the undersurface of the flap.
- Once the lower border of the teres major is identified, a more careful

dissection is required to safely expose the pedicle exiting the triangular space between the teres major inferiorly and the teres minor superiorly.

- The pedicle gives off small branches to the teres major and minor that require care for ligation.
- After the pedicle is shown entering the flap, the remaining proximal incisions are completed to create a flap island (**TECH FIG 1C**).
- Separating the teres major and minor with a self-retaining retractor and abduction of the arm facilitates dissection of the flap.

Lateral Approach (Antegrade, Proximal to Distal)

- Proximal flap incisions are made first in the vicinity of the triangular space along the preoperative markings. The deltoid, triceps, and teres muscles are exposed.
- The deltoid is retracted cephalad and the CSA is identified at the hiatus between the teres major and minor.
- The direction of the transverse and descending branches is confirmed.
- The skin paddle can then be adjusted if necessary and centered over the vascular pedicle under direct vision as the dissection proceeds from proximal-to-distal direction.
- Once the distal incisions are made, the skin island is isolated on the CSA pedicle.
- The pedicle is completely dissected and the vessels are separated in anticipation of flap harvest. It is important to complete pedicle dissection *prior* to osteotomies because the bleeding from the cut bone edges will complicate this process.

TECH FIG 1 • **A.** The scapular skin paddle has been partially elevated and retracted laterally with a skin hook. **B.** The scapular skin paddle has been reflected laterally. The skin hook is retracting the parascapular skin paddle to be elevated next. **C.** Both scapular and parascapular flaps have been completely islandized.

■ Inclusion of Latissimus Dorsi Muscle

- A portion of the latissimus or serratus anterior fascia can be included in the flap based on the shared blood supply of these structures with the flap.
- Dissection of the pedicle to include the takeoff of the TDA and the serratus anterior branches is performed.
- This dissection enables transfer of a large soft tissue component that can be used to repair complex defects of the head and neck.

■ Bone Harvest

- Bone harvest continues in a similar fashion with both the lateral and medial

approaches to skin flap harvest.

- The multiple muscle branches from the CSA are carefully divided as the dissection continues into the triangular space.
- It is important to avoid dissection between the CSA and lateral border of the scapula.
- The teres muscles and the infraspinatus muscle are divided 2 to 3 cm medial from the lateral border down to the scapular bone along the intended vertical osteotomy line (**TECH FIG 2A**).
- The muscles are then elevated off the lateral scapula leaving a muscular cuff to avoid injury to the periosteal blood supply (**TECH FIG 2B**).
 - This is especially true as the lateral border of the scapula is approached where 1 cm of muscle cuff is left attached to bone.
- The divided teres muscles are reflected laterally.
- The vascular branches to the lateral border of the scapula are identified and preserved (**TECH FIG 2C**).
- The periosteum is sharply divided along the vertical osteotomy line and elevated medially. A saw or an osteotome is used to cut through the bone (**TECH FIG 2D**).
- The inferior transverse osteotomy is made first (**TECH FIG 2E**).
- The vertical osteotomy is parallel to the lateral border and extends from 1 to 2 cm below the glenoid fossa/shoulder joint superiorly to the planned distance inferiorly (**TECH FIG 2F**).
- During the superior transverse osteotomy between glenoid fossa superiorly and the CSA inferiorly, great care is taken to avoid injury to these structures (**TECH FIG 2G**).
- The bone is then everted laterally to allow easy detachment of the underlying subscapular muscle by similarly preserving a muscular cuff on the bone (**TECH FIG 2H**).
- If the tip of the scapula is to be included, the angular artery is identified, preserved, and traced to its junction to the serratus branch or the TDA itself. The serratus anterior insertion to the tip is divided leaving a muscle cuff.
- Any bleeding from the muscle cuff of the bone flap is controlled with bipolar cautery.
- The CSA and its comitant veins are traced proximally toward their junction with the thoracodorsal artery and its accompanying vein (**TECH FIG 2I**).

TECH FIG 2 • A. Both scapular and parascapular skin paddles have been reflected laterally exposing the circumflex scapular artery (CSA). The origins of teres major (*TM*) and teres minor (*Tm*) muscles from the lateral border of the scapula have been divided to expose the underlying bone (lateral scapula). Please note the infraspinatus muscle (*IsM*) retracted medially. **B.** The periosteum is elevated along the planned vertical osteotomy line. **C.** An osteotome is used to perform the inferior horizontal osteotomy. The scapular and parascapular skin paddles have been reflected superiorly to expose the underlying lateral osseous flap. The lines point to the vascular supply of the flaps—musculoperiosteal (lateral osseous), descending (parascapular), and transverse (scapular) branches, respectively. **D.** Due to the periosteal vascular supply, the osteotomies should be performed with great care. The periosteum should be minimally

stripped at the planned osteotomy site. Multiple contouring osteotomies might jeopardize the blood supply to the bone. Inclusion of the angular artery would “supercharge” the osseous flap allowing more than one osteotomy. The osteotomies are performed in the following sequence: inferior transverse (**E**), vertical (**F**), and superior transverse (**G**). **H**. After the osteotomies (*dashed line*) are completed, the lateral osseous flap is elevated to allow division of the subscapular muscle attachments. **I**. A closeup view of the subscapular artery and vein (SSA&V) branching into the thoracodorsal artery/vein (TDA/V) and circumflex scapular artery/vein (CSA/V). Note the very short length of the subscapular vein. In this case, two separates venous anastomosis might be required, especially if there is a valve at the short segment of the subscapular vein.

- The subscapular pedicle is then followed proximally to the axillary vessels, and any remaining branches are ligated.
- It is important to preserve the nerves to the surrounding muscles during this dissection.
- The pedicle is divided at an appropriate length.
- The donor site has to be closed, before the flap can be inset.
- In the meantime, if available, a second surgeon can prepare the flap at the back table (osteotomy, vessels). This will allow more expeditious inset and revascularization.
- After division of the pedicle, the donor-site closure begins with reattachment of the divided muscles to the remaining scapular bone.
 - Two or three drill holes allow suture fixation of the cut muscle ends to the edge of the scapula.
- Large-bore suction drains are placed in the axilla and the back.
- With adequate undermining, most defects can be closed primarily in two layers. Otherwise, skin grafts are used as necessary.

■ Preparation and Inset of the Flap

- The osseous component of the flap is cut to appropriate length and osteotomized as necessary to match the mandibular defect.
- Because the blood supply of the scapula flap is based on periosteal perforators, care should be taken to avoid stripping the bone for osteotomies. In addition, the number of osteotomies should be minimized as much as possible to avoid bone necrosis.
- In addition, because the periosteal blood supply is critical, the periosteum should be maintained in continuity during the osteotomies by careful, limited elevation.
- Osteotomy is made with a small reciprocating saw or fine burs while shielding the periosteum.
- If a prebent and appropriately marked reconstruction plate is available, this can be done even before the division of the pedicle.
- Alternatively, the flap can be prepared either by a second surgeon at the back table while the donor site is being closed or immediately before inset.
- However, it is best done before revascularization to avoid tension to or accidental avulsion of the pedicle. Plating is best done at the time of the inset.
- If the defect is small or access to it is limited, the flap destined to provide intraoral lining can be completely or partially inset prior to bone fixation.
- Osteosynthesis with the native mandible can be achieved with a single reconstruction plate spanning the entire defect. Alternatively, small plates or interosseous wires can be used.
- Microvascular anastomosis is completed in the standard fashion.
- Finally, soft tissue inset is completed.

■ Flap Variations

Medial Osseous Flap

- An osteocutaneous flap can be harvested from the medial border of the scapula between the scapular spine and the inferior angle. The corticocancellous segment is 10 to 12 cm long and 2 to 3 cm wide.
- The blood supply is provided from fascial attachments of the dorsal thoracic fascia on the undersurface of the scapular flap to the underlying bone.

- Nevertheless, the bone is thinner on the medial border of the scapula (1.5 cm as compared to 3 cm on the lateral aspect) providing less bone stock.

Inframammary Extended Circumflex Scapular (IMECC) Flap

- It is yet another option of skin paddle design that can be combined with the lateral osseous flap to better disguise the scar in women.
- The flap is centered over the anterior branch of the superficial CSA that arises from the descending branch a few centimeters below the triangular space and turns toward the ipsilateral inframammary fold.

Isolated Angular Bone Segment

- The inferior angle of the scapula can be harvested as an isolated bone segment in combination with any of the skin paddle options to reconstruct composite mandibular defects of appropriate size.
- The angular branch can arise from the TDA itself, the serratus branch, or the latissimus dorsi branch. It reaches the scapula on top of the serratus muscle and beneath the TM.

Additional Options

- Several additional flaps can be elevated with the osteocutaneous flap on the same subscapular pedicle:
 - Latissimus dorsi muscle
 - Latissimus dorsi myocutaneous flap (**TECH FIG 3**)
 - Latissimus dorsi muscle with rib
 - Dorsal thoracic fascia flap
- Simultaneous elevation of serratus flaps is discouraged, as it is an important muscle for shoulder stability.

TECH FIG 3 • A. All the components of a composite osteomusculocutaneous flap are shown. **B.** Another patient is shown in right lateral decubitus position with both the scapular and latissimus dorsi skin paddles islandized. The scapular osteocutaneous flap will be used for mandibular reconstruction and intraoral lining. On the other hand, the fleur-de-lis skin paddle and underlying latissimus dorsi muscle (latissimus dorsi musculocutaneous [LDMC] flap) will provide external coverage of the lower jaw and allow release of a neck contracture. **C.** On the same patient, the scapular skin paddle is reflected to expose the underlying lateral osseous component of the flap.

Axillary incision	■ A counter incision in the axilla or extension of the existing incision toward the axilla, though not necessary, will allow identification and dissection of the subscapular vessels in a safer and more rapid manner.
Skin over the triangular space	■ The triangular space should be included in all skin flap geometries to ensure optimum blood supply.
Skin island configurations	■ When the scapular flap is combined with a parascapular flap, they can be raised in continuity in a reverse L-shaped configuration (with de-epithelialization performed as necessary) or as two separate skin islands.
Pedicle length	■ The effective maximum pedicle length for the lateral osseous flap is 4–6 cm (subscapular artery plus CSA up to the periosteal branches). Lateral osseous bone to scapular or parascapular skin paddles 2–3 cm.
Lengthening the pedicle	■ When suitable recipient vessels are found only on the contralateral neck: ■ The TDA is harvested distally to an appropriate length and used as the donor artery to provide blood supply in a reverse flow fashion. ■ For venous outflow, either the SSV with a vein graft (reversed thoracodorsal vein is readily available) can be used or the cephalic vein can be transposed.
Simultaneous recipient vessel dissection	■ In the lateral decubitus position, a second surgeon could explore ipsilateral neck vessels simultaneously.
Additional soft tissue	■ Subcutaneous dissection beyond the skin border can provide additional soft tissue, if facial contouring is necessary.
Tissue expansion	■ Pre-expansion can allow primary closure of larger than usual flaps. Otherwise, postoperative expansion of the surrounding skin can allow resurfacing of a previously grafted area.
Primary closure of large parascapular defect	■ A pedicled TDA perforator flap has been described for closure of a large parascapular flap defect in an attempt to avoid skin grafting.

Scapular vs parascapular skin island	■ If only one skin paddle is required, parascapular flap can be preferred over the scapular flap as it facilitates the axillary exposure for dissection of the pedicle and allows placement of the scar in a less conspicuous area.
Skin grafting	■ Skin grafting at the donor site invariably results in poor graft take, significant contour irregularity, and conspicuous scar.
Flap thickness	■ The flap may be thick in obese individuals. This should be taken into consideration during planning of flap dimensions.
Dental rehabilitation	■ If osteointegrated implants are planned for dental rehabilitation, careful planning of the inset is necessary. The graft orientation should be such that the bone segment with the optimum height and width is placed at the area of interest.
Anatomic variations	■ In case of double CSA or CSA/CSV that do not join the SSA/SSV, additional recipient vessels are required if any additional tissue is to be carried on the TDA. ■ If the pedicle of the parascapular flap (CSA descending branch) courses behind the TM, the TM has to be divided during the harvest of the skin island.

POSTOPERATIVE CARE

- The shoulder/arm is kept immobilized for 1 week to allow healing and minimize pain.
- First, range-of-motion exercises are carefully initiated followed by shoulder girdle muscle strengthening exercise 2 to 3 weeks after surgery.
- The donor site requires 3 to 4 weeks to heal completely.

OUTCOMES

- Although shoulder function limitation has been reported in the literature, adhering to a meticulous technique and postoperative rehabilitation regimen can prevent this complication.⁸
- In large series of 105 patients undergoing osseous scapular flap harvest, Gibber reported no such complication.⁹
- For various reasons, still only a minority of patients eventually undergo placement of osteointegrated implants irrespective of the implantability of the reconstructed bone segment.
- Anatomic studies have demonstrated bone stock amenable to implantation in 78% to 95% of specimens.¹⁰
- Potential complications include

- Hematoma
- Seroma
- Wound infection or dehiscence
- Widened scar at the donor site
- Limitation of shoulder movement and strength
- Nonunion of mandibular reconstruction
- Brachial plexus or long thoracic nerve injury

Lateral Mandible Reconstruction With Soft Tissue Flaps

13

CHAPTER

Afshin Mosahebi, Evan Matros, and Babak J. Mehrara

DEFINITION

- The mandible provides contour to the posterior lower third of the face and plays a key role in mastication and maintenance of oral competence.
 - As a result, mandibular function is necessary for swallowing, speech, and aesthetic contour of the face.
- The most common indication for mandibular reconstruction is segmental bone loss resulting from cancer ablation, trauma, osteoradionecrosis, and infection.
- Defects of the lateral mandible are defined as those that extend posteriorly from the mental foramen and can include the ramus or condyle.
- Lateral mandibular defects that are most suitable for soft tissue–only reconstruction defects include not only osseous defects but also extensive soft tissue injury including the floor of the mouth, tongue, palate, pharynx, and external skin. Mandibular defects that result in the complete loss of the temporomandibular joint and the surrounding soft tissues may also benefit from soft tissue–only reconstruction because inseting of bone flaps in these defects may be difficult and associated with poor function.

ANATOMY

- The mandible is anatomically divided into one horizontal component and two vertical components.
 - The horizontal component comprises the symphysis and the body on each side, forming a U-shaped arch that connects the two vertical segments.
 - Each vertical segment is composed of the angle, ramus, coronoid process and condylar process. The vertical segment serves as the insertion site for the

muscles of mastication and forms the articulation of the mandible with the skull.

- The arterial supply of the mandible is derived from branches of the lingual, facial, and inferior alveolar arteries.
- The inferior alveolar nerve is the largest branch of the mandibular nerve. It enters the mandible through the mandibular foramen on the medial surface of the mandibular ramus and gives two terminal branches: the mental nerve and the incisive nerve.
- The mental nerve innervates the skin of the chin as well as the skin and the mucosa of the lower lip.
- The incisive nerve continues to travel in the mandible and provides sensory innervation to the premolar, canine, incisor teeth, and their associated gingiva.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient history should include careful assessment of the pathology of the anticipated mandibular defect and the previous treatments that have been administered.
- History of prior surgery, particularly those that may involve the vascular supply of the mandible, should be obtained. This information is important in surgical planning because damage to the ipsilateral neck vessels may require the use of contralateral neck vessels or alternative plans.
- Surgical plans should be reviewed with the head and neck surgeons (if they are involved in the procedure).
- History of radiation to the area should also be obtained because this treatment may impede healing of soft and bony tissues, decrease availability of recipient vessels, and increase the potential need for external skin coverage.
- Past medical history, medical comorbidities, and risk factors for cardiovascular disease (eg, hypertension, coronary artery disease, hyperlipidemia, history of smoking, obesity, diabetes, etc.) should be reviewed.
- This is common in patients with head and neck cancers because many of these individuals have a history of smoking and ethanol use.
- Patients with long-standing history of cardiovascular disease require medical consultation for preoperative clearance and optimization.
- Preoperative speech and swallowing should be documented and assessed because these functions may be significantly affected by tumor invasion and surgical ablation. In addition, preoperative mouth opening should be recorded as interincisal distance.

- Oral hygiene and dentition should be assessed because patients with poor oral hygiene and dentition are at much higher risk of postoperative infections and complications. Severe compromise of dentition or oral hygiene may also require preoperative dental consultation.
- The presence or absence of pain with mouth opening, chewing, swallowing, or eating should be obtained.
- The patient's general nutritional status should be assessed by physical examination and laboratory tests.
- Personal and family history of bleeding abnormalities should be elicited.
- The physical examination should also include assessment of the head and neck area, anticipate the planned resection in the case of oncologic patients, assess availability of recipient vessels, quality of intraoral and extraoral soft tissues, and available donor sites for reconstruction.
- A pulse examination of the extremities is necessary to document the potential for peripheral vascular disease.
- The quality (ie, thickness, pliability, etc.) of soft tissue donor sites should be addressed, and alternative plans should be developed.

IMAGING

- Preoperative computed tomography (CT) or magnetic resonance imaging (MRI) may be helpful in assessing osseous defects and potential involvement of the soft tissues.
- Preoperative angiography may also be helpful in assessing availability of recipient vessels in the head and neck area, although this is rarely necessary.
- Preoperative imaging of donor sites may also be useful for assessment of blood flow. However, this is rarely necessary for assessment of soft tissue flaps such as the anterolateral thigh or rectus abdominis flaps commonly used in soft tissue only reconstruction of complex lateral mandible defects.

SURGICAL MANAGEMENT

- Lateral mandible defects that involve primarily the bone with limited resection of the soft tissues are best reconstructed with bone flaps (eg, fibula, scapula, iliac crest).
- Soft tissue reconstruction of lateral mandible defects is indicated in patients with an intact anterior mandibular arch (ie, bone resection is lateral to the incisors) in combination with complex soft tissue defects involving the floor of the mouth, tongue, palate, pharynx, or, in some cases, external skin.

- It is useful in cases in which the temporomandibular joint is widely excised, leaving a large defect at the base of the skull where bone flaps cannot be adequately seated.
- It may be needed in patients who do not have osseous donor-site options (eg, severe peripheral vascular disease). However, this is less common because multiple options for bone donor sites exist (eg, scapula may be a good choice in these cases).
- Of the variety of soft tissue flaps useful for reconstruction of complex lateral mandibular defects, the vertical rectus abdominis myocutaneous flap and the anterolateral (ALT) flap are most commonly used for the following reasons:
 - They provide large amounts of soft tissues and muscle that can be tailored to complex defects.
 - They enable harvesting of multiple skin paddles that can facilitate combined intraoral and extraoral defect reconstruction.
 - They have long pedicles that can easily reach neck recipient vessels even if it is necessary to use vessels contralateral to the site of the defect.

Preoperative Planning

- The defect is evaluated for reconstruction, taking into consideration the volume of tissues necessary to maintain the remaining mandible in anatomic position.
 - The need for intraoral and extraoral (if necessary) tissue reconstruction is assessed.
- Factors that are important in planning reconstruction of lateral mandibular defects:
 - Medical comorbidities, functional and nutritional status, and oral hygiene
 - Extent of the mandibular defect
 - Anticipated soft tissue defects
 - Prior surgical procedures and availability of recipient vessels
 - The need for postoperative adjuvant therapies that may be necessary
 - Planned or anticipated secondary/tertiary reconstructions

Positioning

- The patient is positioned in supine position.
- In most cases, a tracheostomy is also performed because emergent reintubation of a patient with an extensive reconstruction involving the lateral mandible may be challenging and may result in iatrogenic injury to the free flap.

TECHNIQUES

■ Horizontally Oriented Flaps

- It is generally simplest to orient the flap horizontally along the axis of the defect thus interposing the soft tissue flap between the cut end of the mandible and the infratemporal fossa.
- This orientation results in optimal positioning of the vascular pedicle with respect to the neck vessels.
 - If the ipsilateral neck vessels are used, the flap is oriented with the vessels exiting the flaps posteriorly.
 - Conversely, if it is necessary to use the contralateral neck vessels, the flap is oriented with the vessels exiting the tissues medially (thus decreasing the distance necessary to reach the contralateral vessels).
- The patient shown in **TECH FIG 1A** has undergone a radical resection of the right hemimandible, retromolar trigone, floor of the mouth, and partial tongue for a recurrent squamous cell cancer involving the retromolar trigone area.
 - Because the temporomandibular joint was resected, and the patient had a paucity of recipient vessels preventing double free flap reconstruction, the defect was reconstructed with a vertical rectus abdominis myocutaneous (VRAM) flap (**TECH FIG 1B**).
 - The flap has been inset into the defect in the horizontal plane, thus obliterating the defect in the mandible and maintaining normal positioning of the remaining bone and, at the same time, obliterating the intraoral soft tissue defect (**TECH FIG 1C**).
 - Rigid fixation with plates is rarely necessary in this type of reconstruction. Plates placed in this manner routinely fail (necessitating additional surgery) and complicate flap inset resulting in compression or pressure on the flap.
 - Microsurgical anastomosis was performed to the right superior thyroid artery (end to end) and the internal jugular vein (end to side). In general, the inset is performed at least partially to stabilize the flap followed by microsurgical anastomosis.

TECH FIG 1 • **A.** Extensive lateral mandible defect (lateral mandible, floor of the mouth, lateral tongue, retromolar trigone, and temporomandibular joint) in a patient treated for a recurrent squamous cell cancer. **B.** Markings for a large VRAM flap. **C.** Flap inset demonstrating horizontal orientation of the flap to reconstruct the floor of the mouth, retromolar trigone, and mandibular defect.

■ Nonhorizontally Oriented Flaps

- It may be necessary to orient the flap slightly off axis or in a more vertical direction. This most commonly happens when there is a combined intraoral and extraoral defect.
- The patient shown in **TECH FIG 2A** had a recurrent squamous cell cancer of the right hemimandible with regional metastasis to the lateral cheek, floor of the mouth, and retromolar trigone.
- Resection of this recurrence resulted in an extensive intraoral and extraoral defect involving the lateral mandible, floor of the mouth, buccal mucosa,

retromolar trigone, and external cheek skin (**TECH FIG 2B**). A fibula flap alone would not be suitable for this reconstruction and would necessitate a double free flap, which, given this patient's medical comorbidities and nutritional deficits, was not advisable.

- A VRAM flap with a double skin island was designed to reconstruct all the defects with one flap (**TECH FIG 2C**).
- The flap was inset in a primarily vertical orientation with the skin paddle and muscle obliterating the mandible defect and the inferior skin paddle inset into the intraoral defect (**TECH FIG 2D-F**).
- Note watertight closure of the defect.

TECH FIG 2 • A. Recurrent squamous cell cancer of the lateral mandible involving the cheek and retromolar trigone. Note abnormal adherence of the tongue to the buccal mucosa and the preoperative absence of the right marginal mandibular nerve function. **B.** An extensive resection resulting in a complex intraoral and extraoral defect has been performed. **C.** Double-island VRAM flap is planned and drawn in place with approximate measurements of the skin paddles needed for reconstruction. **D.** Flap positioning prior to inset. Note almost vertical orientation lining up the inferior portion of the flap intraorally. **E.** Flap has been inset into the intraoral defect. **F.** Final flap inset demonstrating closure of both intraoral and extraoral defects.

PEARLS AND PITFALLS

Planning	■ The plan should be discussed with the ablative surgeon preoperatively because preservation of the anterior mandibular arch is necessary. ■ Dental consultation is helpful in patients with carious teeth. ■ Preoperative imaging may be necessary to assess the extent of the expected defect and availability of recipient vessels.
Recipient site preparation	■ Recipient vessels should be preserved during resection and prepared prior to flap transfer. ■ The defect should be carefully analyzed to design the optimum flap and the best combination of skin, muscle, and fat to meet the volume and soft tissue requirements of the defect.
Flap inset	■ Flap can be inset vertically or horizontally to best obliterate the intraoral and extraoral (if present) defects. ■ Orientation of the flap with respect to recipient vessels should also be considered.
Donor-site closure	■ A two-team approach allows flap inset and donor-site closure simultaneously, thus cutting down time under anesthesia.
Postoperative care	■ The head should be kept neutral to minimize stress on the closure. ■ Drains should be kept away from the anastomoses. ■ Circumferential tracheostomy ties are strictly avoided as they can compress the pedicle.

COMPLETION

- The neck wound is copiously irrigated with warm saline or antibiotic solution and the position of the vessels is confirmed with gentle ranging of the neck to ensure that the vessels do not become kinked with patient motion.
- One or two closed suction drains are placed in the neck with care taken to avoid compression of the vein or suction near the anastomosis.
- Skin wounds are closed after loose approximation of the platysma (if possible) and skin closure with nylon sutures (4.0).

POSTOPERATIVE CARE

- Tube feedings are begun within 48 hours of the conclusion of the procedure. Irrigation of the oral cavity for hygiene is generally begun after 3 days.
- The tracheostomy is left in place for 10 to 14 days, or until wound healing is assured and it is clear that additional surgery is not needed.
- Extensive defects, particularly those involving reconstruction of the pharynx or retromolar trigone may benefit from swallow studies to ensure that there is no leak into the neck and that the patient does not aspirate oral feeds. These are usually done approximately 2 weeks postoperatively.
- Patients who have extensive surgery in combination with a prior history of radiation may benefit from longer recovery times (eg, 6 weeks) with swallow assessment performed as an outpatient. In these cases, oral feeds are maintained with nasogastric or, more commonly, gastric tubes.

OUTCOMES

- The use of soft tissue reconstruction alone for extensive defects allow patients to return to an oral diet relatively quickly.¹
- Mosahebi et al. evaluated 76 patients who underwent soft tissue reconstruction of extensive posterolateral mandibular defects.
 - VRAM was used most commonly (89%) and mean length of stay was 18 days.
 - Most patients (54%) were able to tolerate oral feeds at discharge, and 60% had normal or near normal speech.
 - Aesthetic outcomes were good in 49%, fair in 21%, and poor in 30%.
 - Salivary fistulas developed in 6.6% of patients and healed spontaneously in over 80% with conservative management.
- Kroll et al.² reported on 21 patients treated in a similar manner with most patients achieving good to excellent aesthetic outcomes, and excellent speech and swallowing in 33%.
 - Most patients required secondary revisions to address neck fullness.

COMPLICATIONS

- Potential complications are related to flap failure (generally less than 5%), infections, hematoma, intraoral wound dehiscence (which may lead to orocutaneous fistula formation), or functional complications (eg, impaired speech, swallowing, mastication).
- Flap donor-site complications may also be problematic in this patient population.

CHAPTER Maxillomandibular Fixation

Cherry L. Estilo, SaeHee Kim Yom, and Joseph Randazzo

DEFINITION

- Maxillomandibular fixation (MMF), also called intermaxillary fixation, involves fixation of fractures or residual components (following surgical resection) of the mandible or maxilla by applying elastic bands or stainless steel wire between the maxillary and mandibular arch bars.
- Occlusion is the relationship between the maxillary and mandibular teeth as they contact one another. In this chapter, the term “occlusion” refers to the occlusion when the jaw is closed.

ANATOMY

- MMF serves two purposes:
 - To stabilize and align the jaws into appropriate occlusal relationship to maintain preoperative occlusal status
 - To assist in maximizing the precision of the reconstruction
- Presence of full or near-full complement of healthy dentition (especially, in the posterior region) is ideal for successful MMF.

PATIENT HISTORY AND PHYSICAL FINDING

- A thorough oral and dental clinical examination is completed.
- The periodontal status of the teeth and the condition of existing restorations or fixed prosthesis are evaluated to determine the ideal teeth for fixation.
- The occlusal relationship and any mandibular deviation are noted.

IMAGING

- Along with clinical examination (**FIG 1A**), a panoramic radiograph (and selected dental radiographs, if necessary) examination is completed to assess

the overall health and stability of the patient's dentition.

- When indicated, selected dental (periapical or bite-wing) radiographs are obtained (**FIG 1B**).

SURGICAL MANAGEMENT

- Equipment (**FIG 2**)
- Erich arch bars

FIG 1 • A. Occlusion prior to mandibular resection. **B.** Periapical radiograph.

- Stainless steel ligature wire (24 gauge)
- Wire cutters
- Needle holders
- Band pusher
- Elastics (red rubber whistle tip catheter size 14 French, cut in 3-mm thickness)

FIG 2 • Tools necessary for MMF.

TECHNIQUES

■ Intermaxillary Fixation

- The patient's preoperative occlusal relationship is confirmed.
- The preoperative imaging is reviewed.
- The Erich arch bars are measured and cut to fit the contour of the remaining dentition of the maxilla and mandible.
- The ligature wires are cut to approximately 15 cm (for posterior and 1–2 cm shorter for anterior teeth) and stretched to prevent loosening after placement.
- The arch bar is placed on the maxilla and mandible with the lugs positioned apically (**TECH FIG 1**).
- The arch bar is anchored to periodontally sound teeth by passing the ligature wire through the interproximal space and circumferentially fixed by twisting the two ends together in a clockwise direction until tight.¹
- A band pusher is used to assist in placing the ligature wire as apically as possible on the lingual/palatal aspect to ensure a secure fit.
- The excess length is cut leaving the terminal segment (approximately 1.5 cm), which is then curved to form a rosette to prevent trauma to the adjacent soft tissue.
- Following application of the arch bars, the bars are tested for stability. At least three wire loops are usually employed to ensure proper fixation.
- Elastic bands are placed on the opposing lugs of the maxilla and mandible to

complete the fixation in appropriate occlusal relationship.

TECH FIG 1 • A. Placement of arch bars on the mandible and maxilla. Note apical and opposite orientation of the lugs. **B.** Placement of bands on arch bars completing MMF.

PEARLS AND PITFALLS

Indication	■ To maintain preoperative occlusal status
Technique	■ Arch bars are cut to the appropriate size and bent to the shape of the mandible and maxilla. ■ Arch bars should be securely affixed to the mandible and maxilla. Loose bars can be uncomfortable and may result in loss of alignment. ■ Band pushers are helpful for this. ■ Wires are cut short and capped with bone wax or other material to avoid injuring/irritating the lips.
Postoperative care	■ Topical anesthesia is very helpful and facilitates removal of the bars. ■ Radiographic evaluation may be performed to confirm proper alignment and healing. ■ Oral hygiene is important to avoid infections and pain.

POSTOPERATIVE CARE

- The Eric arch bars are removed approximately 1 week following placement (or when fracture healing has been confirmed in cases where the mandible fracture

is not repaired with plates/screws, and MMF is used as the primary means of repair).

- Dental x-rays may be obtained to confirm proper alignment of the mandible (**FIG 3A**).
- Prior to removal of the Erich arch bars, topical anesthetic may be applied to the gingival area or local anesthesia provided via gingival infiltration for patient's comfort.
- The ligature wires are cut with either a wire cutter or high-speed handpiece and removed with a needle holder.
- The arch bars are released and removed from the maxilla and mandible.
- The oral cavity is carefully inspected to ensure that it is free of debris and materials (**FIG 3B**).
- The oral cavity is carefully irrigated using saline and suctioned.
- Postoperative panoramic radiograph is obtained.
- Following removal of MMF, the patient is advised to maintain a soft diet and to chew on the contralateral side.

FIG 3 • A. Postoperative panorex image demonstrating fibula flap for reconstruction and restoration of occlusion. **B.** After removal of arch bars, occlusion is maintained.

- Oral hygiene instructions are provided to include brushing all remaining teeth after meals and at bedtime using an ultrasoft toothbrush.

OUTCOMES

- In most cases, MMF has excellent outcomes and patients recover satisfactorily. Irritation and discomfort are common and should be treated symptomatically;

in most cases, the bars are removed in a week.

- MMF may decrease ventilatory capacity and should be used with caution in patients with reduced pulmonary function particularly if the airway is not secured.²

COMPLICATIONS

- The technique of MMF is safe and, in general, well tolerated.
- Complications related to MMF are relatively rare and include pain, gingivitis/periodontitis, and irritation of the buccal mucosa.
- Malocclusion is a potential complication but is more commonly related to the techniques used for mandibular stabilization. If MMF alone is used for the treatment of mandibular fractures, then malocclusion may occur particularly in poorly aligned comminuted fractures.

Section VI: Lip

15 Repair of Lip Commissure Defects with Estlander Flaps

CHAPTER

Simon G. Talbot and Julian J. Pribaz

DEFINITION

- Defects of the lips may occur from malignancy (most frequently squamous cell carcinoma followed by basal cell carcinoma), trauma, vascular malformations, or infections.¹
- There is disagreement in the literature about terminology.
 - Here, we refer to a lip switch flap *not* involving the commissure (either lower to upper lip as originally described or vice versa) as an Abbe flap.
 - We refer to a lip switch involving the commissure (either upper to lower or vice versa, as both were described in the original paper) as an Estlander flap.
 - We have chosen to not use the terms “reverse Abbe” and or “Abbe-Estlander,” which are sometimes used elsewhere to refer to upper to lower flaps excluding the commissure.

ANATOMY¹

- The lips include multiple layers of tissue: skin/subcutis, muscle, submucosa, and mucosa.
- The vermilion forms a wide boundary between the mucosa and skin. Meticulous repair of the white roll (the external border of the vermilion and skin) is critical as defects in this border are easily noticed.
- Lip function is controlled by the orbicularis oris muscles (sphincteric function) and numerous muscles of facial expression (elevation and depression functions).
 - Elevators include levator labii superioris, levator anguli oris, zygomaticus

major and minor, levator anguli superioris, and mentalis muscles.

- Depressors include depressor anguli oris, depressor labii inferioris, and platysma muscles.
- Key external landmarks of the lips include Cupid's bow, the philtral columns, the central tubercle, the white roll, and the commissure.
- Arterial supply is through the facial artery branching into the superior and inferior labial arteries. These run just deep to the mucosa in the submucosal layer just deep to the orbicularis oris muscle, at the level of the mucosal-vermilion junction (**FIG 1**).
- Venous drainage does not follow the arterial pattern, but a dense plexus exists in the lips.
- Sensation is supplied by the infraorbital branch (upper lip) and mental branch (lower lip) of the trigeminal nerve.
- Motor function to the orbicularis oris is supplied by the buccal branches of the facial nerve.
 - Additional muscles of facial expression are supplied by the zygomatic and mandibular branches.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Because of the unique anatomy and appearance of the lips, when defects involving the lips are too large to close directly, local flaps using the similar-appearing “like tissue” from the opposite lip are ideal.
- Estlander flaps are suited for patients presenting with a full-thickness defect of the lateral lip up to and including the commissure.
- Defects up to a quarter of the upper lip and one-third of the lower lip can usually be closed directly.
 - Flap closure is more appropriate for defects of half to three-quarters of the upper or lower lip (**FIG 2**).
 - Larger defects may require additional or distant flaps.
- Similar to an Abbe flap, the Estlander flap is a cross-lip flap. However, whereas the Abbe flap can rotate clockwise or anticlockwise based on either labial artery, the Estlander flap rotates around the commissure and can be based only on the contralateral labial artery as the ipsilateral vessel has usually been removed with the tumor extirpation.
- A second-stage procedure to divide and inset the flap and re-establish the commissure is required, and this can be safely done at 3 to 4 weeks.

- Estlander flaps can be used to reconstruct either upper or lower lip defects.²

Cross-section of lip showing labial artery

FIG 1 • Cross-sectional anatomy of lower lip.

FIG 2 • Defect after Mohs resection of infiltrating basal cell carcinoma.

IMAGING

- Imaging may be required for oncologic workup or as indicated by trauma. However, for operative planning, no imaging is necessary.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative markings may be aided by the use of a template (a sterile Esmarch is ideal for this purpose).
- Unlike with an Abbe flap, markings for an Estlander flap should not traverse the vermillion, as this will subsequently form the new oral commissure.

Positioning

- A nasal intubation is preferred with the tube secured to the nasal septum using an absorbable suture.
- The operating table is turned 90 degrees away from the anesthesiologist with the operative side of the mouth toward the center of the room. A standard head drape is used.

Approach

- A superiorly or inferiorly based flap can be performed depending on the location of the defect.

TECHNIQUES

■ Estlander Flap for the Upper Lip

- Incisions should use natural skin creases, such as the mental crease where possible.
- The triangular flap should be marked and should be the same height and half the width of the defect (to share the horizontal deficiency between the upper and lower lips).

- A concurrent cheek advancement flap (and a Burow triangle resection from the lateral alar/medial cheek) reduces the defect and size of flap/donor site required (**TECH FIG 1A**).
- Often, the Burow triangle is not resected but used as an inferiorly based flap that is advanced medially with the cheek flap and can be useful to repair the nostril sill (**TECH FIG 1B**).
- Needlepoint cautery allows precise dissection.
- The labial artery must be preserved. This should not be skeletonized to preserve a sufficient plexus of veins for drainage.
- The flap is rotated about the commissure and sutured in place.
- A layered closure is performed taking care to approximate the orbicularis oris and precisely close the vermilion at the white roll (**TECH FIG 1C,D**).
- Later, a commissure-plasty in which the base of the flap is divided and inset and the commissure re-established is required (**TECH FIG 1E**).

TECH FIG 1 • **A.** Operative markings. **B.** Advancement of Burow flap. **C.** Estlander flap elevation and transposition. **D.** Final flap inset. **E.** Division and inset of flap with commissure-plasty.

■ Estlander Flap for Lower Lip

- A case showing Estlander flaps used for the lower lip is shown in **TECH FIG 2**.

TECH FIG 2 • A. Patient with loss of lower lip post necrotizing infection. **B.** Upper lip-to-lower lip Estlander flap. **C.** After commissure-plasty.

PEARLS AND PITFALLS

Hemostasis	■ Good hemostasis is critical to prevent this highly vascular area from ongoing bleeding.
Pedicle	■ The labial artery must be preserved and not skeletonized; maintenance of adequate mucosa aids with venous drainage.
Technique	■ If congestion occurs, the flap inset can be taken down and a delayed inset performed when choke vessels have opened.
Technique	■ A concurrent cheek advancement flap can reduce the size of the defect and flap/donor site required.
Technique	■ A Schuchardt advancement using an incision in the labiomental fold can additionally help with closure of a lower lip defect.
Caveats	■ Smoking can severely impair vascularity of the flap and should be strictly avoided both preoperatively and postoperatively.

FIG 3 • A,B. Postoperative appearance of the patient in **TECH FIG 1** after division and inset with commissure-plasty. **C.** Preoperative smile. **D.** Postoperatively, she has elevator weakness due to loss of levator labii superioris during tumor excision.

POSTOPERATIVE CARE

- Bacitracin ointment is applied to suture lines.
- Sutures are removed at 7 to 10 days.
- Stretching of the mouth is avoided until full healing.

OUTCOMES

- The Estlander flap provides a relatively simple reconstruction of large defects of the lateral upper or lower lip involving the commissure (**FIG 3A,B**).
- Minor revisions may be required, including resuspension and tightening of lip elevators and revision of any contractures at the commissure to improve symmetry and widen the aperture.
- Sensory and motor recovery occurs over months in the order of pain, touch,

and temperature.³

- Because of rearrangement of the surrounding muscles of facial expression, animation may be altered (**FIG 3C,D**).

COMPLICATIONS

- Arterial compromise or venous congestion may occur if vascularity is not maintained.
- When more than half the width of the lip requires reconstruction, this flap may not be large enough to prevent significant microstomia.

16 Repair of Lip Defects With Karapandzic Flaps

CHAPTER

Simon G. Talbot and Julian J. Pribaz

DEFINITION

- Defects of the lips may occur from malignancy (most frequently squamous cell carcinoma followed by basal cell carcinoma), trauma, vascular malformations, or infections.
- A Karapandzic flap is either a single/unilateral or a paired/bilateral innervated musculocutaneous rotation flap used to reconstruct subtotal lower lip defects.
- A reverse Karapandzic flap can be used to reconstruct an upper lip defect. Combined upper and lower lip defects have been reconstructed with simultaneous upper and lower flaps.
- Midline defects are preferred for this method of reconstruction; lateral or commissure defects may result in significant asymmetry.

ANATOMY

- The unique anatomy of the lips make the use of adjacent “like” lip tissue ideal for reconstruction.
- The lips include multiple layers of tissue: skin/subcutis, muscle, submucosa, and mucosa.
- Karapandzic flaps maintain continuity and innervation of the orbicularis oris muscle. This is an advantage over flaps that replace a lip defect with cheek tissue excluding the orbicularis.
- The vermilion forms a wide boundary between the skin and mucosa. Meticulous repair of the white roll (the external border of the vermilion and skin) is critical as defects in this border are easily noticed.
- The original description of the Karapandzic flap references the robust labial artery circulation.¹

- In the very old, irradiated, or those requiring bilateral flaps, the labial artery alone may be insufficient, hence the benefit of keeping an intact mucosa for additional vascularity when designing Karapandzic flaps.
- The modiolus can be thought of as a circle, and a defect in this circle may be closed by rotating the remaining edges around the circumference to close the defect.
- Reapproximation of the orbicularis oris and preservation of the buccinator along with maintenance of nerves allows for early intrinsic muscle function (**FIG 1**).
- Some authors recommend the use of a nerve stimulator to help protect native innervation.²

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients will present with a large, subtotal, or total lip defect.

FIG 1 • Facial nerve anatomy and distribution of perioral facial nerve branches to be preserved in Karapandzic flap.

IMAGING

- Imaging may be required for oncologic reasons but is not routinely required for flap planning.

SURGICAL MANAGEMENT

Preoperative Planning

- Markings include a skin incision parallel to the lip margin; the vertical dimension of the flap is determined by the vertical dimension of the lip defect (**FIG 2**).

FIG 2 • Preoperative appearance and markings for unilateral Karapandzic flap.

- The flaps are extended laterally and vertically. Where possible, incisions are hidden in the melolabial folds and/or mental crease.

Positioning

- A nasal intubation is preferred to prevent distortion of the lips. The endotracheal tube should run vertically upward to avoid interference with the operative field.
- The operating table is turned 90 or 180 degrees from the anesthesiologist. A standard head drape is placed.

Approach

- A single or bilateral Karapandzic flap may be sufficient for medium to large lip defects.
- Where this is inadequate, combinations of Karapandzic flaps and an Abbe flap may be needed.
- Extended Karapandzic flaps may also facilitate larger defects to be reconstructed. This technique uses medial cheek elements (as an extension of the primary flaps) to form the central lower lip elements with a mucosal advancement forming the vermillion.³

TECHNIQUES

■ Bilateral Karapandzic Flaps for Closure of Large Midline Lower Lip Defect

- Markings are drawn as described (**TECH FIG 1A**).
- Judicious local anesthesia with epinephrine can be used to aid hemostasis but should be kept away from the facial artery pedicle.
- Marked incisions are made, and dissection proceeds carefully through the subcutaneous fat (**TECH FIG 1B**).
- The facial artery is located deep to the facial muscles and enters the skin from below. Similarly, the branches of the facial nerve are located deep to the musculature. These branches are dissected bluntly (often with a mosquito) preferably with loupe magnification.
 - In this manner, the skin, subcutaneous tissues, and facial muscles are incised, but the nerves and vasculature beneath the muscle are preserved (**TECH FIG 1C**).
 - Blunt dissection may be possible in the deeper and more superior aspects of the cheek incisions to easily maintain these structures (**TECH FIG 1D**).⁴
- Although the facial and labial arteries will stretch significantly, if sacrifice is needed, flap vascularity may be maintained on an intact, large mucosal pedicle (**TECH FIG 1E**).
- Only the advancing 2 to 3 cm of the mucosa is incised but the rest is left intact, to help with perfusion and venous drainage.

- Mucosa, muscle, and skin are closed in layers.
- For the donor area, the skin incision is repaired but the incised muscle is left free, thus preventing tension on the closure of the flap.
- An intrinsic discrepancy between the cheek and flap lengths can be minimized with excision of the Burow triangles (**TECH FIG 1F–H**).

TECH FIG 1 • **A.** Markings for bilateral Karapandzic flap. **B.** Bilateral flap incisions are made. **C.** Neurovascular bundles are preserved. **D.** Flaps are elevated on neurovascular pedicles, maintaining mucosa where possible. **E.** Flap transposition. **F.** Removal of the Burow triangles offsets the discrepancy between the cheek and flap lengths. **G,H.**

The incisions are closed in layers.

PEARLS AND PITFALLS

Hemostasis	■ Local anesthesia with epinephrine can be injected away from the pedicle.
Pedicle	■ Visible facial artery branches and nerves should be kept intact with careful blunt dissection using loupe magnification. ■ Perfusion and venous drainage is maintained by not dividing mucosa excessively, just the advancing edge.
Technique	■ Excision of the Burow triangles can help share length discrepancies while closing.
Caveats	■ Smoking can severely impair vascularity of the flap and should be strictly avoided both pre- and postoperatively.

POSTOPERATIVE CARE

- Bacitracin ointment is applied to external suture lines.
- Sutures are removed at 7 to 10 days.
- Stretching of the mouth is avoided until full healing.
- No specific therapy is required.

OUTCOMES

- In patients with large initial defects, this technique can lead to microstomia. However, this is relatively uncommon due to the elasticity of normal lip tissue.
- Using “like” lip tissue and intrinsic musculature for this reconstruction is typically superior functionally and esthetically to using distant flaps.
- There is tightness of the lower lip with lack of projection relative to the upper lip, which improves with time and with subsequent fat grafting and vermilion advancement (**FIG 3**).

COMPLICATIONS

- Microstomia may be corrected with a staged commissureplasty. This can be performed through a Y-to-V flap or through excising a lateral wedge and advancing mucosal flaps.

- Effacement of the gingivobuccal sulcus can occur and may be revised with a skin graft internally in the sulcus.²

FIG 3 • **A.** Early postoperative appearance. **B.** Appearance and function may be improved with fat grafting and mucosal advancement. **C.** Late postoperative appearance and function.

17 Repair of Lip Defects With the Abbe Flap

CHAPTER

Robert Beinrauh and Joseph H. Dayan

DEFINITION

- A full-thickness portion of the lower lip, which includes the mucosa, orbicularis oris muscle, and skin with vermillion, based on the right or left inferior labial artery with mucosal venous attachments¹
- Used in reconstruction of defects of the upper lip (which do not involve the commissure) between one-third and one-half of the entire lip
- A reverse Abbe flap (Estlander-Abbe flap) is the exact same flap only taken from the upper lip to reconstruct lower lip defects not involving the commissure.
- We will use the technique for the traditional Abbe flap for this chapter, but recognize the reverse flap is the same technique based on the superior labial artery.

ANATOMY

- The lips are a sphincter composed of a concentric ring of mucosa, muscle, and skin, which form a tight seal to prevent liquid from escaping the oral chamber and also to produce the labial sounds used in speech.
- Orbicularis oris muscle:
 - A circumferential ring of muscle around the mouth that functions to compress and purse the lips together
 - The muscle fibers run horizontally on the upper and lower lips and begin at the modiolus.
 - There is an oblique extension of the muscle that runs from the commissure to the anterior nasal septum and nasal floor.
- The inferior labial artery branches from the facial artery at the angle of the

mouth.

- The artery runs inside the lip several millimeters inferior and anterior to the vermillion/mucosal junction of the posterior lip² (**FIG 1**).

PATHOGENESIS

- Lip deformities can be congenital or acquired.
- Congenital deformities are most commonly cleft lip defects.
- Acquired deformities are most commonly due to traumatic or neoplastic etiologies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Abbe flap is an excellent choice for defects of up to approximately 50% of the upper or lower lip.
- Upper lip defects of 25% or less and lower lip defects of 33% or less can be closed primarily. However, the Abbe flap may be useful even in these relatively small defects if the philtral column is involved and requires reconstruction.

FIG 1 • Cross section of the lip showing inferior labial

artery.

- Lip defects larger than 50% of the lip may require either larger flaps, staged reconstruction, or a flap from a distant tissue site. However, there is some patient-to-patient variability in these size considerations due to anatomic considerations (ie, the baseline size of the lower lip) and the degree of skin laxity.
- The Abbe flap is used for defects that do not involve the lip commissure. The Estlander flap is more useful for more lateral defects that involve the commissure. Abbe flap is excellent for reconstruction of bilateral cleft lip patients with scarred or short philtrums.³

IMAGING

- No imaging is necessary for the Abbe flap. However, a pencil Doppler can be helpful to confirm position of inferior labial artery.

SURGICAL MANAGEMENT

Preoperative Planning

- Size of the defect and layers of lip involved must be assessed.
- The orbicularis oris muscle must be reconstructed to restore lip competence and avoid cosmetic deformities (eg, whistle deformity) with lip movement.
- In general, the size of the lower lip Abbe should be less than 30% of the width of the lower lip to avoid microstomia. However, as noted, there is some variability based on skin laxity and anatomic considerations.

Positioning

- Supine position and prep as for any facial procedure

Approach

- Measure defect and use template of the wound to design the resection size of the lower lip.
- The flap should be designed so that it will easily rotate into the defect without tension.
 - The flap should be located in an area with similar vermilion thickness as the edges of the defect.
- Make the horizontal size of the lower lip flap dimension 50% of the horizontal

size of the upper lip defect.⁴

- Do not make the inferior extent of the flap extend beyond the mental crease.
- Drive the incision laterally along the mental crease.
- Note position of inferior labial artery with Doppler prior to incision.

TECHNIQUES

■ Donor-Site Preparation

- Use of loupe magnification for the procedure is recommended.
- The donor site should be prepared first.
- Freshen the edges if needed with a no. 15 blade scalpel and create hemostasis with cautery.
 - Use a 25-gauge needle dipped in methylthioninium chloride to mark the white roll of your defect as well as of the lower lip.
 - The incision at the vermilion should be a perpendicular cut so that the Abbe flap will approximate into the vermilion in a straight line.
- Measure the recipient site width. The lower lip flap markings should be approximately half this diameter of the defect (**TECH FIG 1**). Avoid harvesting a very narrow (less than 0.5 cm) flap.
- The vertical extent of the defect should match the Abbe flap exactly.

TECH FIG 1 • Markings for Abbe flap donor site.

■ Recipient Site Preparation

- Mark out the Abbe flap to your specifications.
- Use a 25-gauge needle dipped in methylthioninium chloride to mark the white roll of your defect as well as of the lower lip.
 - Mark the white roll where you will incise with the methylene blue and then mark the white roll on either side of the incision so that you will have a guide to approximate the white rolls during the approximation of the Abbe flap into the defect as well as approximation of the donor site white roll following rotation of the flap (**TECH FIG 2A**).
 - Take care not to incise through the mental crease of the chin pad. Drive this incision laterally (**TECH FIG 2B**).
 - The donor flap should be located opposite the defect to facilitate easy rotation.
- Keep the pedicle as lateral as possible when the donor site is closed to allow the patient to eat and drink for 2 weeks while the pedicle is maintained.
- Doppler the artery on the side of the inferior lip at the site that will retain the pedicle.
- Use 2 to 3 cc of local anesthetic with epinephrine in the inferior portion of the flap to maintain a bloodless dissection.

TECH FIG 2 • A. The white rolls are marked with methylene blue at both the donor and recipient sites to facilitate approximation. **B.** The scar should be driven laterally at the mental crease.

■ Raising the Flap

- Begin the dissection on the nonpedicle side of the lower lip flap.
- Compress the inferior labial artery with one hand and have the assistant hold the lip opposite to the mark to compress the other side of the inferior labial artery.
- Incise the skin and vermilion with a no. 15 blade scalpel.
- Use needle-tip cautery to cauterize each end of the inferior labial artery.
 - Use this opportunity to note the position of the artery to the mucosa and vermilion as it will be analogous to the more important contralateral pedicle side.
- Dissect the nonpedicled side through the muscle and the mucosa with the cautery to achieve a through-and-through separation of tissue.
- As you begin the incision of the pedicle side of the flap, make an incision through the anterior portion of the vermilion and white roll as well as the skin.
 - Do not incise too deep at this point.
 - Only through the skin and dermis

- Begin the dissection of tissue at the inferior aspect of the flap and work your way superiorly.
- As you near the pedicle, stop using cautery and begin to slowly spread the tissue in a horizontal direction with blunt tip tenotomy scissors.
- Release only the amount of orbicularis oris muscle that is needed to facilitate rotation at this time.

TECH FIG 3 • The posterior vermilion and mucosa are kept intact around the inferior labial artery for rotation.

- Leave the posterior vermilion and mucosa intact around the inferior labial artery (**TECH FIG 3**).
- The artery does not need to be visualized.
- Use a Doppler to monitor position of the inferior labial artery as necessary.

■ Flap Placement and Closure

- We prefer temporary closure of the lower lip donor site with a 4-0 Vicryl

(Ethicon, Branchburg, NJ) to help facilitate the rotation (**TECH FIG 4A**).

- Replace this suture with the 5-0 Prolene (Ethicon, Branchburg, NJ) at final closure.
- Once the flap is rotated, suture the white roll together using 5-0 Prolene (Ethicon, Branchburg, NJ) suture.
 - This placement must be as exact as possible.
- Suture the vermillion of the flap to maintain its thickness and position.
- Suture the mucosa in horizontal mattress fashion.
 - The closure of the donor site mucosa is important to make watertight so as not to develop leakage of saliva.
- The orbicularis oris is closed next using 4-0 Vicryl suture.
- The dermal layer is closed using 5-0 Monocryl suture.
- The skin is then approximated using 5-0 Prolene suture in an interrupted fashion.
 - Dissolvable suture can be used for this step in small children who will not tolerate suture removal postoperatively.
- The lower lip donor site is closed in an identical fashion (**TECH FIG 4B**).

TECH FIG 4 • A. Rotation of the Abbe flap into the recipient site. The donor site has been temporarily closed. **B.** Final closure of both sites, showing the pedicle.

PEARLS AND PITFALLS

Patient selection	■ Abbe flap is not a good option if the defect involves the commissure or resection of the lower lip will exceed about 30% of the total lip as microstomia may result.
Design	■ The flap must be designed to facilitate rotation into the defect. Failure to do this will result in tension on the pedicle and ischemia.
Technique	■ Leave the inferior labial artery pedicle together with the posterior vermilion and mucosa to facilitate venous drainage as well as to avoid tension and kinking of the artery.
Closure	■ It is essential to approximate all of the lip elements as well as possible during the first procedure. ■ The second-stage surgery will have scar tissue and swelling to contend with, which will hinder achievement of a good cosmetic result.
Ischemia	■ If flap shows signs of ischemia upon rotation, place flap back into original position and treat it as a delay. Attempt rotation again in 10–14 days.

FIG 2 • Results 2 months postoperatively at rest (**A**) and with mouth open (**B**).

POSTOPERATIVE CARE

- There is no need to place additional fixation to keep the mouth shut.
- The patient may have a full liquid diet.
 - Start with a clear liquid diet postoperatively to avoid emesis.

- Use antibiotic ointment 3 times a day.
- Division of the pedicle should occur at approximately 14 to 21 days.
 - Restoration of white roll of vermillion of both upper and lower lip should be done at this time if it was not completed at the first stage.
 - Revision of the lower lip donor vermillion can be done at this stage.
 - Reserve revision of the upper lip Abbe flap until the future when a more adequate blood supply is established (**FIG 2**).

COMPLICATIONS

- Injury to the inferior labial artery pedicle
- Microstomia
- Ischemia of the flap upon rotation
- Infection
- Salivary leak
- Inadequate cosmetic restoration of vermillion lip elements
- Scarring of the donor site

18 Lower Lip Reconstruction With the Nasolabial Flap

CHAPTER

George D. Xipoleas and Matthew S. Kilgo

DEFINITION

- The nasolabial flap is a versatile random pattern superiorly or inferiorly based flap that can be used to reconstruct defects of the lower lip.^{1–3}
- The nasolabial flap can be used to reconstruct defects spanning the entire transverse dimension (approximately 7 cm) of the lip.
- In most cases, the flap can be used to reconstruct the entire vertical dimension (approximately 2.0 cm) of the lower lip.

ANATOMY

- The lower lip is composed of the intraoral mucosa, vermilion, and skin/subcutaneous tissue extending inferiorly to the labiomental fold.
- The most distinguishing feature of the lip is the vermilion, a modified mucosa that covers the free margin of the lip and is adapted to external exposure.
 - There are relatively few salivary glands beneath the vermilion in contrast to the mucosa.
- Musculature of the lower lip (**FIG 1A**)
 - The body of the lower lip is predominantly composed of the orbicularis oris.
 - The primary muscle responsible for oral competence. It compressed and protrudes the lips and creates the oral sphincter.
 - The orbicularis oris muscle has two points of origin.
 - The peripheral fiber originates from the modiolus where they interdigitate with the fibers of the adjacent muscles of facial expression (buccinators, levator anguli oris, depressor anguli oris, levator labii superioris, depressor labii inferioris, zygomaticus minor, and zygomaticus major). This is

considered the peripheral portion of the muscle.

- The central fibers are restricted to the lip proper and are considered the labial portion of the muscle.
- The muscle fibers interdigitate in the midline and insert into the mucosa.
- The mentalis muscle elevates and protrudes the lower lip.
 - Originates from the incisive fossa of the mandible
 - Inserts into the skin of the chin
- The depressor labii inferioris muscle draws the lower lip downward and laterally.
 - It originates from the mandible adjacent to the mental foramen.
 - It inserts into the skin of the lower lip.
- Innervation of the lower lip (**FIG 1B**):
 - Motor innervation to the lower orbicularis oris is from the marginal mandibular and buccal branches of the facial nerve.
 - Motor innervation to the depressor labii inferioris and mentalis is from the marginal mandibular branch of the facial nerve (cranial nerve 7).
 - Sensory innervation of the lower lip is from the mental branch (V3—third division) of the trigeminal nerve (cranial nerve 5).
- Blood supply of the lower lip (**FIG 1C**):
 - Paired lower labial arteries that are branches of the facial artery
 - They course horizontally across the lip in the submucosal plane, posterior to the orbicularis muscle at approximately the same level as the anterior vermilion line.
- Lymphatic drainage (see **FIG 1C**):
 - Drainage occurs via the submandibular and submental lymph nodes.
- The nasolabial crease is an anatomic landmark created by the insertion of the superficial muscular aponeurotic system (SMAS) into the skin junction of the cutaneous lip and the cheek.
 - Marks the division of the cheek lateral to the fold and the lip and nose medial to the fold
 - Medial to the crease, the skin of the lip is tightly attached to the orbicularis oris muscle.
 - Lateral to the crease, the skin of the cheek is loosely attached to the deep muscular fascia, and there is an abundance of subcutaneous tissue and skin laxity.

PATHOGENESIS

- The majority of lip defects in adults are secondary to excision of malignant tumors. Other causes of lip defects include vascular malformations, congenital defects, and trauma.
- Neoplasms of the lip are primarily related to actinic changes.
- Upward of 90% of lower lip neoplasms are squamous cell carcinomas (SCCs) with the remainder being made up of basal cell carcinomas (BCCs), salivary gland carcinomas, and melanomas.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history and physical examination are important to determine the type of lesion and intervention.
- The physical examination should be directed not only to the lips but to the oral mucosa and to the lymphatic drainage basins, ie, the submandibular and submental nodes.

FIG 1 • A. Musculature of the face. **B.** Motor and sensory innervation of the face. **C.** Blood supply and lymphatic drainage of the face. The nasolabial flap is a random pattern flap and does not need a perforating blood vessel to be found for viability of the flap.²

- What is the patient's age, sex, and skin type?
 - Cancers of the lip are most common in lighter skin males in their sixth decade. There is a 6:1 ratio of SCC in males to females.
- Does the patient have a history of prolonged or repeated sun exposure?
 - Sun exposure is the most important risk factor in the development of skin cancers.
 - One-third of patients have outdoor occupations or outdoor pastimes.
 - The lip is susceptible to metaplasia because it lacks the pigmented layer for protection.
- How did the lesion present, how long has the lesion been present and how has the lesion changed?
 - Patients will typically report a history of a nonhealing "scabbed" or "crusted" lesion that bleeds when the scab is removed.
 - Long-standing lesions with no changes in size or characteristics are less likely to be malignant.
 - Long-standing nonhealing wounds are more likely to be malignant.
 - Increases in size, changes in color, consistency, and mobility may be an indication of malignant degeneration.
- Where is the lesion located? Is it mobile or fixed? Is there any associated adenopathy?
 - It is important to determine the location of the lesion and the structures involved:
 - That is, the vermilion, mucosa, or muscle
 - Most tumors grow slowly and may be freely mobile, whereas others will grow rapidly, infiltrating adjacent tissue.
 - In the lower lip, perineural spread along the mental nerve can also occur.
 - In the lower lip, SCC is much more common and will spread via lymphatic drainage to the submandibular or submental nodes.

IMAGING

- Imaging will be dictated by the pathology of the lesion. If the lesion is benign or a basal cell carcinoma, imaging is usually not necessary because it does not typically spread to distant sites. If the lesion is a more aggressive tumor, imaging may be appropriate.
- CT scan or MRI can be used to determine local/regional spread into the soft tissue and lymph node basins.
- A panorex can be undertaken if the tumor is felt to be fixed to the mandible or if there are paresthesias in the mental nerve distribution.

DIFFERENTIAL DIAGNOSIS

- Most lesions of the lower lips are malignant SCC. Biopsy should be undertaken to determine the identity of the lesion. The differential includes both benign and malignant lesions.
- Basal cell carcinoma
- Melanoma
- Sebaceous adenoma (benign)
- Hemangioma (benign)
- Venous lake (benign)
- Pyogenic granuloma (benign)
- Merkel cell carcinoma (malignant)
- Dermatofibrosarcoma protuberans (malignant)
- Microcystic adnexal carcinoma (malignant)

NONOPERATIVE MANAGEMENT

- Radiation therapy is a nonoperative treatment option for basal cell or squamous cell cancers that may be useful for patients who cannot undergo surgical excision of malignant lesions or are not suitable reconstruction candidates due to medical comorbidities or other factors.
- Radiation has an equivalent 5-year survival when compared to surgery in lesions that are less than 3 cm in diameter.
- Radiation, however, may result in local tissue changes that may complicate reconstruction if surgical excision is necessary.
- Cryotherapy or curettage may also be possible depending on the pathology of the lesion.

SURGICAL MANAGEMENT

- Basal cell carcinoma:
 - Nodular type BCC can be excised with 2-mm margins.
- Squamous cell carcinoma:
 - Lesions less than 1.5 cm in diameter can be excised with 10-mm margins.
- In both the cases of BCC and SCC, Mohs surgery can be employed.
- Melanoma:
 - In situ lesions—5-mm margins
 - Up to 1 mm depth—1-cm margins
 - 1- to 2-mm depth—1- to 2-cm margins
 - 2- to 4-mm depth—2-cm margins
- Definitive reconstruction of the lip should be delayed until the final margins are cancer-free.

Preoperative Planning

- The size of the defect should be evaluated.
- Facial examination should be performed to assess the laxity in the nasolabial crease and the amount of tissue in the nasolabial fold.
- Determination if a unilateral flap or bilateral flaps will be needed. Bilateral flaps can be used to reconstruct the entire width of the upper lip.
- If the patient has vascular compromise or is a smoker, then a delay procedure should be considered.
- The type of anesthesia should be discussed with the planning:
 - Local with sedation vs general anesthesia

Positioning

- The patient is positioned supine on the operating room table.
- The head is stabilized in a foam ring.
- The face is prepped with dilute Betadine.
- Eye shields or Steri-Strips are placed over the lids to protect the eyes.
- The face is draped bilaterally from tragus to tragus and from forehead to chin to visualize the entire face and provide access to both nasolabial folds.

Approach

- Care should be taken that the margins of the lip are negative for malignancy before definitive reconstruction be undertaken.
- Once definitive measurements are known, lower lip reconstruction can

proceed with various techniques. Consideration should be given to the size of the defect and the types of tissue that needs to be replaced.

- Often, smaller lesions can be repaired primarily or with lip advancement flaps, without the use of local tissue flaps.
 - Defects less than 33% of the total lower lip width can be repaired primarily.
- If a local flap is necessary, usually for defects greater than 33%, care should be taken to consider what type of tissues are missing.
 - If the mucosal aspect of the lip has been violated, mucosal advancement flaps can be used to resurface the area of the wet/dry border of the lip.
 - Local cheek, lip, or nasolabial flaps can be used unilaterally or bilaterally to reconstruct large defects.³

TECHNIQUES

- A banner-shaped flap is designed in the nasolabial fold with the nasolabial crease serving as the medial border and superior border of the flap.
 - The width of the flap, at its widest point should not exceed 2.5 cm in middle-aged people (**TECH FIG 1**); however, the width can be increased to 3.5 cm in the elderly due to increasing skin redundancy and laxity.
 - The flap is based immediately superior to the lateral aspect of the defect to minimize the creation of a standing cutaneous deformity. Placing the flap base superiorly and laterally to the commissure prevents downward traction on the flap.
- The flap is injected with 1% lidocaine with epinephrine to aid in hemostasis and is elevated in the subcutaneous plane. The distal tip is tapered for ease of closure of the donor site.
 - Meticulous hemostasis is obtained with the bipolar electrocautery.
 - The donor site may be undermined for tension-free closure and is repaired in a layered fashion with deep absorbable sutures and cutaneous permanent sutures removed within 1 week.
 - A 0.5-cm portion of the donor site may be left open at the pivot point to reduce the amount of tension on the flap.
- The flap is transposed into the lip defect and sutured in place with deep absorbable sutures consisting of cutaneous absorbable sutures on the mucosal side of the defect and interrupted permanent sutures on the skin surface.

- If the commissure remains intact, the pedicle can be divided 10 to 14 days after the transfer. Longer time periods may be required for patients who have been previously treated with radiation or have scarring of the periorbital area.
- In defects that are vertically short, a single flap may suffice to adequately restore the full lip height.
- When larger vertical defects exist, bilateral flaps may be interposed to reconstruct the vertical dimensions of the lip, with one flap serving as skin coverage and the other as lining.

TECH FIG 1 • A. The width of the flap (y) should not exceed 2.5 to 3.5 cm, depending on the age of the patient. **B.** If the height of the defect (y) exceeds 2.5 to 3.5 cm, or if the length of the defect (x) exceeds 7 cm, bilateral nasolabial flaps should be used to cover the defect adequately.

PEARLS AND PITFALLS

Local anesthesia

- Use local anesthesia with epinephrine for vasoconstriction.

Blood supply

- The nasolabial flap has a robust subdermal blood supply. There is no need to incorporate a named vessel into the flap.

Delay the flap when necessary	■ If the vascularity of the flap is questionable, lay back down into the donor site and perform delay procedure.
Do not short-change yourself	■ The nasolabial flap has distinct dimensions. If the defect is larger than the unilateral nasolabial flap will accommodate, use bilateral nasolabial flaps.
Pathology	■ Proper pathology is needed for margins. Do not perform the procedure unless the margins are cancer free.
Hemostasis in the lip	■ Obtain meticulous hemostasis in the lip wound bed. A hematoma in the lip bed could compromise the flap.

POSTOPERATIVE CARE

- The procedure may be performed as an outpatient.
- The patient applies bacitracin BID to the suture lines.
- Normal oral hygiene is maintained.
- Chlorhexidine swish and spit is added as well to the oral regimen.
- Liquid diet is prescribed for 3 days followed by soft diet for 2 weeks after which the patient returns to a normal diet.

OUTCOMES

- Functional oral aperture without microstomia
- Normal oral hygiene and use of dentures
- Aesthetically acceptable results
- Normal speech

COMPLICATIONS

- Include
 - Oral incompetence
 - Drooling
 - Flap loss
 - Tight lower lip if flap is designed too small

19 Lip Reconstruction With Radial Forearm Free Flap

CHAPTER

Vishal Thanik

DEFINITION

- Lip reconstruction is restoration of form and function after loss from a number of causes, the most common being oncologic resection and trauma.
- The lips are critical functional units in the processes of speech and alimentation and are one of the prime conveyors of emotion in the human face. They are also a focus of beauty in cultures worldwide.
- Reconstructive options in lip reconstruction are determined primarily by size and location of the defect; as defects become larger in more critical locations, functional outcome becomes paramount and aesthetic quality diminishes.
- Smaller defects typically can be addressed with local flaps, and in general, the use of free flaps is reserved for defects that cannot be reconstructed with local tissue alone.

ANATOMY

- The lips are a trilaminar structure containing mucosa, muscle, and skin.
- External anatomy (**FIG 1A**)
 - Upper lip—base of nose to nasolabial fold
 - Lower lip—mental crease to nasolabial fold
 - Corners of the lip referred to as commissures
 - Skin transitions to mucosa at the vermilion border, with the transition skin referred to as the white roll.
 - Midline of the upper lip has a curve referred to as the “Cupid’s bow.”
 - Cupid’s bow progresses vertically to the philtrum, a depression that is bordered on either side by the philtral columns.
 - The vermilion is a specialized mucosal surface that does not contain minor

salivary glands.

■ Internal anatomy (**FIG 1B**)

- Muscular anatomy of the lip functions as a specialized sphincteric system.
- Orbicularis oris forms a sphincteric ring and is the major muscle of the trilaminar structure.
- Major elevators of the lip are the zygomaticus major and levator anguli oris, with zygomaticus minor and levator labii superioris as secondary elevators.
- Major depressor of the lip is the depressor anguli oris, with contributions from the depressor labii inferioris, mentalis, and platysma.
- The modiolus is just lateral to the commissure and is the confluence of muscle fibers to the dermis, the functional insertion of the levator and depressor muscles.

■ Innervation

- Sensory innervation to the upper lip is provided by the maxillary branches of the trigeminal nerve, whereas the lower lip is supplied by the mandibular branches.
- Motor innervation is via branches of the facial nerve.

FIG 1 • A. External anatomy of the lip. **B.** Musculature of the lip.

■ Vascular supply

- The facial artery is the main blood supply to the lip and branch, diving and entering the lips laterally, becoming the superior and inferior labial arteries. These vessels can run between the mucosa and orbicularis muscle or through

the muscle depending on the patient.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Understanding the underlying etiology of the defect is paramount. Traumatic wounds can generally be reconstructed immediately after adequate debridement and ruling out of concomitant injuries that could delay treatment. With oncologic defects, margin status and need for further excision or adjuvant therapy should be assessed prior to reconstruction.
- A full history should be established, with particular attention paid to previous lip/facial reconstruction, smoking and comorbid status, and any history of radiation therapy of the head and neck.
- Physical examination requires assessment of the defect and the surrounding tissues.
 - Assessment of the size and location of the defect, as well as the size of the opposite, typically normal lip
 - Evaluation of the depth of injury, including status of the orbicularis oris
 - Evaluation of the opposite lip for concomitant injury, typically in trauma
 - Neurovascular examination, inventorying sensibility and perfusion of the remaining lip
 - Evaluation of donor sites if free flap reconstruction is warranted

IMAGING

- Imaging is typically unnecessary prior to lip reconstruction.
- In patients with traumatic lip defects, head CT and C-spine imaging may be performed to rule out concomitant injuries.

Surgical Management

- Operative management of lip defects depends on the location, size, and thickness of the defect.
- Partial-thickness defects of the lip and vermilion, if small (generally less than 30% of the lip), can be converted into full-thickness defects and closed primarily in a V-shaped manner.
- Larger partial-thickness defects of the vermilion that are not amenable to V-excision and closure are best managed with mucosal advancement flaps from the labial or buccal surface. Other options include mucosal V-Y advancement flaps or cross-lip mucosal flaps.^{1,2}
- Large, full-thickness defects of the lip are considered those that are 80% or

more. For defects of this size, free flap reconstruction is usually indicated. Another option in some patients, particularly those who are not free flap candidates, is bilateral nasolabial flaps or other local approaches.

- Lower lip defects are more common than the upper lip defects due to increased sun exposure.
- Full-thickness lower lip defects reconstructed with free flaps are difficult due to the potential for lip incontinence and benefit from suspension of the flap with a tendon or fascia graft. Upper lip defects typically do not require tendon grafting.
- The radial forearm flap is the workhorse flap in lip reconstruction because of its thinness and pliability, ability to easily integrate the palmaris tendon, and long pedicle length, which facilitates anastomosis in the neck or superficial temporal system.^{3,4}
- Other flap options include anterolateral thigh flap, parascapular flap, and lateral arm flap. In thin individuals, rectus abdominis and gracilis have also been described.⁵⁻⁷
- Innervation of the flap can be achieved by harvesting the lateral antebrachial cutaneous nerve with the flap and coapt to the mental nerve for sensory reinnervation.

Preoperative Planning—Radial Forearm Flap

- Evaluation of potential recipient vessel site should be performed, including assessment if any previous neck dissection has been performed.
- The size of the defect needs to be established. Typically, the remaining edges retract with the cheek, making the defect appear larger than it actually is. The lip edges should be pulled to resting tension, and the opposite lip can be used for confirmation.
- The width of the flap can be undersized somewhat to the size of the defect, but the height should be modestly oversized to compensate for tension by the palmaris as well as postoperative scarring.
- The height of the mucosal and skin defect should both be measured because they are not typically equal.
- Use of a template to size the defect is advised.
- Presence of palmaris tendon should be confirmed by physical examination.
- In the absence of the palmaris tendon, the plantaris tendon or fascia lata can be utilized through a separate site.

- Allen test should be performed on the forearm to ensure adequate perfusion of the first three digits with radial artery occlusion.

Positioning

- The patient should be placed supine. A foam donut is helpful for positioning of the head.
- The nondominant hand should be abducted on an arm board for radial forearm harvest.

Approach

- For radial forearm free flap, a two-team approach can be applied, with one team harvesting the flap while the other debrides and prepares the defect and recipient vessels.

TECHNIQUES

■ Radial Forearm Free Flap

- Based on the designed template, the radial forearm flap should be marked on the nondominant arm.
- Palmaris tendon should be centered at the junction between the mucosal and skin elements, ie, the fold-over point.
- The radial artery is placed on the side of the flap that will be the external skin.
- Cephalic vein is typically marked and included in the flap if possible.
- Flap is raised under tourniquet control after limb elevation.
- Circumferential incisions are made into the subcutaneous fat; care is taken to identify and preserve the cephalic vein and lateral antebrachial cutaneous nerve.
- Dissection begins on the ulnar border of the flap in a subfascial plane. Dissection proceeds radially in this plane with care taken to preserve the paratenon.
- When the palmaris tendon is encountered, its most distal portion at the palmar aponeurosis should be identified and divided, leaving a cuff of palmaris distal to the distal flap edge.

- Dissection proceeds in a deeper plane incorporating the palmaris and its sheath. Once radial to the palmaris, the previous plane can be re-established until the intramuscular septum and radial artery are encountered.
- Dissection now proceeds from the radial incision. The brachioradialis tendon is identified and retracted radially, giving exposure to the septum and radial artery.
- The cutaneous branch of the radial nerve should be protected.
- The distal portion of the radial artery pedicle can be clipped and divided and the septum can be elevated deep to the vascular pedicle. Branches to the periosteum of the radius and to flexor muscles of the forearm should be ligated and divided.
- A lazy-S incision is carried proximally along the ulnar border of the brachioradialis to the origin of the radial artery.
- Distal to proximal dissection continues along the vascular pedicle, cephalic vein, and lateral antebrachial cutaneous nerve.
- Once adequate pedicle length is obtained, the flap is harvested with either tie or double clip.
- Donor site is closed with unmeshed split-thickness skin graft. VAC dressing and splint are applied (**TECH FIG 1**).

TECH FIG 1 • Skin graft closure of the donor site. Note the slightly more proximal location of the skin paddle to allow for increased length of palmaris distally.

■ Recipient Site Preparation and Insetting

- A multitude of recipient vessels from branches of the external carotid system and jugular vein can be utilized.
- If concomitant nodal dissection has been performed, that exposure can be utilized.
- In the absence of neck incision, a transverse neck incision and exposure of the facial artery can be used (**TECH FIG 2A**).
- For inset of the flap, the flap should be folded along the axis of the palmaris tendon (**TECH FIG 2B–D**).
- Suspension of the palmaris sling is routed through the remaining orbicularis muscle and/or modiolus and sutured to itself, allowing for a dynamic suspension (**TECH FIG 2E**).
- Tension on the palmaris is critical, with a slight overcorrection performed.⁸
- Microneural anastomosis of the lateral antebrachial cutaneous nerve and the mental nerve should be performed if available.

TECH FIG 2 • A. Markings for resection and

transverse neck incision for recipient vessel exposure. Nodal dissection can also be performed through this incision, dependent on ablative surgeon preference. **B.** Schematic diagram demonstrating flap orientation for total lower lip reconstruction. **C.** Flap harvested demonstrating axis of fold along the palmaris longus tendon (*yellow arrow*). **D.** Appearance of the flap after mucosal inset and palmaris tensioning. **E.** Final inset and tensioning of flap.

PEARLS AND PITFALLS

Physical findings

- With oncologic defects, margin status and need for further excision or adjuvant therapy should be assessed prior to reconstruction.
- Assessment of the size and location of the defect, as well as the size of the opposite, typically normal lip.
- Evaluation of the depth of injury, including status of the orbicularis oris
- Evaluation of the opposite lip for concomitant injury, typically in trauma
- Ensure that palmaris is present preoperatively by physical examination.
- Preoperative Allen test

Technique

- Defining the defect width and height is critical. The lateral lip edges should be brought into physiologic tension prior to marking the width as to not oversize the defect. The skin and mucosal heights should be measured individually as they are typically different.
- Palmaris tendon should be centered at the junction between the mucosal and skin elements, that is, the fold-over point. The flap can be placed slightly more proximal than typical to increase the length of palmaris distally.
- For inset of the flap, the flap should be folded along the axis of the palmaris tendon (ie, along the width of the flap).

Postoperative	■ Early mobilization is encouraged. ■ Nasogastric or PEG tube should be used for feeding initially. ■ The donor site is typically covered with a split-thickness skin graft with bolster or VAC dressing. Addition of a splint for 7 days is helpful as well.
Complications	■ A watertight closure on the mucosal side is critical; good oral care and frequent examination minimize salivary leak. ■ The majority of complications arise at the donor site, typically the sequelae of loss of the paratenon during flap harvest. Exposed tendon often causes failure of the skin graft and tethering of the tendon with functional diminishment.

POSTOPERATIVE CARE

- Patients routinely stay in the hospital for 7 to 14 days.
- Flap monitoring is performed by experienced nursing and house staff by clinical examination and handheld Doppler. The authors prefer flap checks q 15 minutes × 2 hours, q 30 minutes × 1 hour, q 1 hour × 48 hours, and q 2 hours until day 4.
- Patients typically are out of bed by postop day 1 and ambulating either the same day or on postoperative day 2.
- Oral care with normal saline swish and spit begins on POD no. 3 along with clear liquid diet when sufficient healing has occurred with diet advancing to soft diet on days 5 to 7.

OUTCOMES

- Despite its shortcomings, the radial forearm remains the best option for reconstruction of subtotal lip defects.
- It allows for single-stage reconstruction or skin and mucosa and restores oral competence and adequate stomal size.
- Color match and lack of vermilion are long-term issues. Tattooing can be used to improve cosmetic outcomes by simulating the vermilion.

COMPLICATIONS

- The majority of complications are at the radial forearm donor site.
- Loss of the paratenon during flap harvest is the most common issue. Exposed tendon often causes failure of the skin graft and delay of wound healing. Secondary effects of this complication are tethering of the tendon with

functional diminishment.

- Care must be taken to evaluate the circulation of the hand with an Allen test preoperatively. Failure to recognize an incomplete arch can lead to catastrophic loss of blood flow to the digits.
- Major issues at the recipient site are early salivary leak or tensioning issues of the palmaris graft.
- Overtensioning of the palmaris can lead to bowstringing of the lip and difficulty with eating. Undertensioning can lead to issues with oral competence.

Section VII: Eyelid

20 Direct Closure and Lateral Cantholysis

CHAPTER

Aaron Fay and John Nguyen

DEFINITION

- The primary objectives of eyelid reconstruction are to
 - Restore anatomic alignment and dynamic function of the eyelids
 - Create a stable eyelid margin with acceptable vertical lid height of both anterior and posterior lamellae
 - Maintain adequate eyelid closure
 - Optimize appearance and symmetry
- Full-thickness eyelid defects involving up to one-third of the margin can be repaired by direct closure, depending very much on the age of the patient, though sometimes the addition of a lateral cantholysis is required to allow adequate mobilization of the lateral lid.

ANATOMY

- The eyelids are conceptually considered as the anterior and posterior lamella (**FIG 1**). The anterior lamella consists of skin and orbicularis oculi muscle. The posterior lamella contains tarsus and palpebral conjunctiva.
- The gray line is an important landmark that separates these two lamellas. This line is important for eyelid margin repair and represents the superficial portion of the orbicularis oculi muscle known as the muscle of Riolan. From the eyelid margin to the superior (upper lid) or inferior (lower lid) edge of tarsus, the upper eyelid tarsal plate is approximately 10 mm tall centrally and tapers toward the medial and lateral canthal tendons, whereas the lower eyelid tarsal plate measures approximately 4 mm high and tapers slightly.

- Above the upper eyelid crease, eyelid anatomy is substantially different, where the concept of lamellae begins to break down. The posterior lamella in this anatomic region includes the conjunctiva, Mueller muscle, and the aponeurosis of levator palpebrae superioris. Most authors now consider a “middle lamella” that includes the preaponeurotic fat and orbital septum. This leaves the orbicularis oculi and skin to constitute the anterior lamella.
- The lateral eyelid also incorporates the palpebral lobe of the lacrimal gland. The lower lid contains analogous structures but notably contains a third fat pad laterally (whereas the lacrimal gland occupies that space in the upper lid). The canthal tendons suspend the eyelids medially and laterally and the lacrimal drainage system including the punctum, canaliculus, common canaliculus, and the medially located lacrimal sac.
- Vascular supply to the eyelids is provided by the marginal arcade, near the eyelid margins, and the peripheral arcades, coursing along the superior tarsal edge in the upper lid and along the inferior tarsal edge in the lower lid.
- Palpebral width, on average, measures 30 mm in adults. The lower lid typically rests at the inferior corneal limbus, with the lateral canthus 2 mm higher than the medial canthus. The upper lid rests slightly inferior to the superior corneal limbus with the peak of the upper lid between the medial corneal limbus and the medial border of the pupil.
- The skin of the eyelid is unique in that it is the thinnest skin found anywhere on the body and is devoid of subcutaneous fat, hence an intimate connection with orbicularis oculi, another thin layer covering the orbital septum from lid margin to brow.

PATHOGENESIS

- Eyelid margin defects can be partial thickness or full thickness, may occur at different positions on the eyelid, and most commonly result from trauma in young men.
- Lacrimal injury may concurrently exist, especially when the laceration is in the medial canthal region. This is more common in children.
- Mechanisms include tissue stretch, crush, avulsion, or tear. Tissue loss is rare, so direct closure without the need for cantholysis is typically performed.
- Resection of malignant eyelid tumors (most often basal cell carcinoma, squamous cell carcinoma, and sebaceous cell carcinoma) results in defects of various sizes. Because surgical margins are needed, these surgeries often cause large defects that may require cantholysis when closing primarily.

- Closure of larger eyelid defects requires local flaps such as Tenzel semicircular flap which is discussed in subsequent chapters.

NATURAL HISTORY

- Incomplete closure of eyelid defects can lead to eyelid notching, exposure, entropion, ectropion, trichiasis, corneal injury, eyeball rupture, and corneal blindness.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Assessment of the eyelid defect typically occurs after stabilization of life-threatening conditions in patients with traumatic injuries.
- History should include nature of the injury; type of trauma; the extent of trauma; prior ocular and periocular surgical history; visual changes; tetanus vaccination status of the patient and the assaulting animal in case of bites; recent food or liquid ingestion; and drug allergy. Bite, hook, or clawing trauma may be suggestive of canalicular laceration.

FIG 1 • A. Anatomy of the eyelid demonstrating the components of the anterior and posterior lamellas. **B.** Position of the gray line separating the anterior and posterior lamella.

- A detailed assessment of the defect must include the width, height, and eyelid

layers involved.

- A defect in the medial canthal region requires an additional examination for canalicular and medial canthal tendon integrity; complete eyelid eversion is indicative of loss of canthal tendon attachment.
- In many cases, the medial canthal tendon can be assessed quickly by distracting the upper and lower lid margins laterally and observing the degree of migration of the medial commissure.
- When a laceration appears to involve the medial eyelid, the punctum should be dilated and the canaliculus probed. Superficial-appearing lacerations in this region are notoriously misleading.
- The eyelid is also inspected for scarring or previous incision sites. Prior irradiation, burn injury, or skin conditions such as scleroderma and ichthyosis may limit the amount of skin stretching needed for primary wound closure.
- Laxity of the lid, especially in elderly patients, is also examined as it may facilitate closure and precluding the need for cantholysis.
- In cases of trauma, careful examination for debris or retained foreign bodies or eyeball laceration (“ruptured globe”) is important. Globe injuries typically dictate the timing of lid repair.

NONOPERATIVE MANAGEMENT

- Small eyelid margin defects involving the anterior lamella without lid laxity may heal adequately by secondary intention. Similarly, small lacerations involving only the anterior lamella without significant tension may be amendable to adhesive repair with cyanoacrylate.

SURGICAL MANAGEMENT

- Lid margin reconstruction is one rare instance in that near perfection can be achieved in many cases. Three months after repair, the surgical site can often be undetectable.
- This requires meticulous apposition of anterior and posterior lamellae.
- Horizontal tension should be maximized at the expense of the vertical tension.
- Parallel wound edges perpendicular to the lid margin are desirable, and minimal excision of wound edge tissues should be performed.
- At the completion of the repair, the lid margin should show a mild eversion at the fusion site in order to avoid notching as the healing wound contracts linearly.

- A delayed repair, whether due to late presentation or surgically planned, typically requires debridement of the epithelialized wound edges. In a defect with canalicular involvement, it is best to repair as soon as possible; however, canalicular repair can still be achieved up to 48 hours after initial injury.

TECHNIQUES

■ Wound Preparation

- The wounds and the lateral canthal region, if needed, are infiltrated with 2% lidocaine with 1:100 000 epinephrine.
- After cleansing with ophthalmic povidone-iodine (1:20 dilution), a scleral shell can be inserted for ocular protection.
- Apposition of the wound edges using two toothed Adson forceps will indicate the amount of tension and whether primary closure would require canthotomy and cantholysis.

■ Primary Wound Closure

- The eyelid margin is repaired using 6-0 silk sutures, which are left long and draped away from the wound awaiting incorporation into subsequent skin sutures. These more pliable sutures are less likely to cause corneal injury than a rigid monofilament. Three sutures are placed along the margin—the first through the gray line, second through tarsus, and third through the lash line.
- The suture bites should be equidistant from the wound on each side of the defect, and the vertical excursion of the bite should be longer than the horizontal excursion of the bite to facilitate wound eversion (**TECH FIG 1A–F**).
- The tarsal edges are then apposed and sutured with partial-thickness 6-0 polyglactin suture. In order to pass intratarsal sutures and to avoid the conjunctival surface, the S-14 spatulated needle is preferred. Precise alignment of the tarsal edges will maintain proper apposition of the posterior lamella (**TECH FIG 1G,H**).
- Minor to moderate amount of anterior lamella tension can be relieved with placement of interrupted 6-0 polyglactin sutures through the orbicularis oculi,

particularly at the level of the primary lid crease (**TECH FIG 1I**).

- The skin is closed with 6-0 nylon sutures. The long ends of the lid margin silk sutures are incorporated into the second nylon suture away from the lid margin (**TECH FIG 1J,K**).

TECH FIG 1 • A,B. Full-thickness lower eyelid defect

measuring one-fourth to one-third the length of the lid margin. This type of defect can often be closed using the direct closure method alone. **C,D.** The cardinal suture is placed through the gray line (muscle of Riolan) symmetrical across the defect. The posterior lid margin edge is checked for alignment before accepting this suture. Silk is preferred because it is soft and well tolerated by the ocular surface. **E,F.** Three sutures are placed through the lid margin: the first through the gray line, the second through the tarsus, and the third through the lash line. Each suture is symmetrical as shown in **C**, but need not be equal in dimension. **G.** Lamellar sutures are placed through the tarsus to avoid the conjunctival surface. (Margin sutures not shown here.) **H.** Three silk sutures are tied along the lid margin. Two sutures are shown in the tarsus. **I.** Following tarsal approximation, orbicularis oculi is closed with buried polyglactin sutures. **J,K.** The long ends of the silk sutures are incorporated into the second skin sutures (nylon).

■ Canthotomy and Cantholysis

- A skin incision is made from the lateral canthus toward the lateral orbital rim, approximately 1 cm, running along a lateral canthal rhytide if possible (**TECH FIG 2A–C**).
- Curved Stevens scissors are then used to divide the lateral canthal tendon along its length by following the skin incision down to the lateral orbital rim (**TECH FIG 2D**).
- The scissors are then angled inferonasally to strum and then lyse the inferior crus of the lateral canthal tendon. The cantholysis can be performed progressively until the desired laxity is achieved (**TECH FIG 2E–G**).
- Following completion of the primary wound closure, the skin and orbicularis edges in the lateral canthal region can be closed with 6-0 fast-absorbing gut

sutures (**TECH FIG 2H–J**).

TECH FIG 2 • A. Full-thickness lower eyelid defect measuring one-third to one-half the length of the lid margin. This type of defect can often be closed using direct closure method provided the lateral canthal tendon is released. **B,C.** A linear incision is created with a no. 15 blade, extending 1.5 cm from the lateral commissure toward the orbital rim. **D.** This incision is extended through the lateral canthal tendon using curved Stevens tenotomy scissors to create a full-thickness canthotomy. **E.** Following lateral canthotomy, the tendon is divided into superior and inferior crura or rami. **F,G.** The lateral lid margin is secured with toothed Adson forceps, traction is placed on the inferior ramus of the lateral canthal tendon, and

Stevens scissors are introduced in the space between the myocutaneous flap and conjunctiva to perpendicularly transect the taut inferior ramus close to the orbital rim, which is called cantholysis. The scissors are directed downward (toward the tip of the nose) to approach the inferior ramus of the tendon. This is facilitated by manually distracting the lower eyelid away from the orbital rim in a perpendicular plane. **H.** The lid margin is closed using a series of 6-0 silk sutures. **I.** Tarsus is closed using 6-0 lamellar-style polyglactin sutures in order to avoid damage to the ocular surface. **J.** Following closure of the wound, the lateral canthal angle is reformed using 6-0 nylon or resorbable sutures.

PEARLS AND PITFALLS

Ophthalmic examination

- In trauma cases, a complete ophthalmic examination is critical to avoid missing a ruptured globe injury that would need repair first.
- Obtain a CT scan if there is concern for orbital injury or foreign body.

Technique

- Avoid excessive cantholysis that can cause ectropion or dehiscence.

Suturing

- When placing the cardinal silk suture through the gray line, cross the two ends of the suture and pull in opposite direction while observing the alignment of the posterior edge of the lid margin. If the edge is not perfectly aligned, the suture should be removed and replaced.

POSTOPERATIVE CARE

- Topical antibiotic ointment can be used 3 times per day until first postoperative visit at 1 week.
- Typical ointments are bacitracin ophthalmic preparation or erythromycin ointment.

- The lids may appear tight but will relax overtime with avoidance of manipulation of lid by patients.
- Nylon and silk sutures are typically removed 7 to 10 days after repair.

OUTCOMES

- A smooth lid margin resting at the inferior corneal limbus is desirable.

COMPLICATIONS

- Wound dehiscence may occur with excessive wound tension or when the tissues have been chronically inflamed.
 - Because of the friable nature of a dehisced wound, careful manipulation is required to resuture the already damaged tissue edges.
 - Canthotomy and cantholysis may be needed during dehiscence repair if there is significant tissue tension.
- Eyelid notching can be avoided by ensuring eversion of wound edges at the margin with silk sutures.
- Ectropion may occur as a result of aggressive cantholysis and would need repair with resuspension of the lateral canthal tendon.

21 Tenzel Semicircular Rotational Flap

CHAPTER

John Nguyen and Aaron Fay

DEFINITION

- The Tenzel semicircular rotational flap was initially described by Dr. Richard Tenzel in 1978.¹⁻³
- It is conceptually similar to the classic Mustarde cheek rotation flap but provides better dynamic reconstruction of the various eyelid lamellae with less tissue rearrangement.
- The Tenzel flap utilizes the rotation of a semicircular musculocutaneous flap beginning at the lateral canthus, extending either downward (for upper eyelid reconstruction) or upward (for lower lid reconstruction) to close full-thickness defects of the eyelid ranging from one-third to two-thirds of the horizontal length of the eyelid margin.
- Both the anterior lamella (skin and orbicularis muscle) and the posterior lamellar (tarsus and conjunctiva) are addressed in a single-stage operation. The final postoperative appearance of the flap is superior to skin grafting or the larger Mustarde flap.⁴
- A large defect up to two-thirds of the horizontal length of the lower eyelid can be repaired with the Tenzel semicircular flap.

ANATOMY

- The upper and lower eyelids meet at the lateral canthus, a tendon-ligament complex that is firmly attached to Whitnall tubercle, 2 to 4 mm deep to the lateral orbital rim. The anterior eyelid lamella (skin and orbicularis oculi) is continuous in this region.
- The thin eyelid skin transitions to thicker facial skin that contains subcutaneous fat, and the orbicularis oculi extends approximately 2.5 cm

beyond the lateral orbital rim.

- Posteriorly, the suborbicularis oculi fat lies anterior to the periosteum of the zygomatic bone.
- The periosteum of the orbit (periorbita) and zygomatic bone condense at the orbital rim to form the *arcus marginalis*; the strong periosteum can be useful to provide elevation support for the flap (**FIG 1A,B**).
- Arterial supply is derived from the lacrimal artery, giving rise to the zygomaticotemporal artery, exiting the lateral orbital wall at midorbit, and to the zygomaticofacial artery, running inferolaterally to exit through a small foramen in the zygomatic bone.
- Both the zygomaticofacial nerve and the zygomaticotemporal nerve arise from the maxillary nerve.
- The zygomaticofacial nerve leaves the orbit inferolaterally through the zygomaticofacial foramen along with the artery and supplies the skin of the malar eminence.
- The zygomaticotemporal nerve similarly egresses the zygomatic bone superiorly to supply the anterior temple (**FIG 1C,D**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Eyelid defects occur most commonly from trauma or tumor resection. Other causes include burns and congenital abnormalities.
- Basal cell carcinoma is the most common eyelid malignancy (90%); squamous cell carcinoma, sebaceous cell carcinoma, and cutaneous melanoma are neoplasms that involve the eyelids in order of decreasing frequency.
- The biologic behavior of the tumor should be a key consideration in reconstructing a large eyelid defect as it can affect long-term prognosis.
- Factors such as the size and orientation of the defect, patient age, vascular supply to surrounding tissues, previous treatment (both surgical and radiation), and age of the wound should also be carefully assessed, as any of these can affect surgical plan and outcome.
- The Tenzel flap is most useful when there is sufficient lateral canthal skin laxity and there is at least a small portion of the full-thickness eyelid available on either side of the defect.
- It can be used when there is no tarsus on the lateral side of the defect, but optimal results will require a periosteal flap or tarsal replacement graft such as hard palate mucosa, auricular cartilage, nasal septal chondromucosal graft,

free tarsoconjunctival graft, allograft, or xenograft to provide the stability that is normally provided by the tarsus.

- Without proper structural support, the lateral portion of the eyelid is likely to roll inward, causing chronic ocular surface injury.
- In cases of irradiation or burn injury, the Tenzel flap is preferred over grafting as the flap provides its own vascular supply.

NONOPERATIVE MANAGEMENT

- In general, significant eyelid defects require surgical repair.
- Nonoperative management of large eyelid defect can lead to eyelid notching, scarring, entropion, ectropion, trichiasis, and lagophthalmos with corneal exposure causing corneal injury, infection, eyeball rupture, and blindness.

FIG 1 • Anatomy (A,B), blood supply (C), and sensory nerve innervation (D) of the eyelids.

SURGICAL MANAGEMENT

Preoperative Planning

- Initial analysis begins with estimation of the actual size of the defect by grasping both edges with toothed Adson forceps and pulling them together.
- If the edges are within 1 to 2 mm of one another, primary closure with lateral cantholysis may be all that is required.
- A larger defect up to two-thirds of the eyelid constitutes an excellent candidate for Tenzel flap for reconstruction (**FIG 2**).
- For larger defects, Hughes or Cutler-Beard flaps may be more effective (discussed in separate chapters).

Positioning

- The patient is positioned in the supine position and prepped with Betadine 5% Sterile Ophthalmic Prep Solution.
- A corneal shield is used to protect the eye.

Approach

FIG 2 • Lower eyelid defect resulting from basal cell cancer excision that is suitable for Tenzel flap reconstruction.

TECHNIQUES

■ Tenzel Flap Reconstruction for the Lower Eyelid

Design and Flap Elevation

- Beginning precisely at the lateral canthus, a semicircular superior arching line is drawn with a diameter of approximately 20 to 25 mm extending toward the lateral eyebrow line; the mirror image is used for the upper eyelid reconstruction (**TECH FIG 1A,B**).
 - The area is infiltrated with 2% lidocaine with 1:100 000 epinephrine.
- A no. 15 Bard-Parker blade is used for skin incision.
- Electrodissection using a monopolar electrode with an ultrasharp tungsten tip is performed to undermine and to develop the myocutaneous flap.
- A lateral cantholysis of the inferior crus of the lateral canthal tendon is made beneath the flap and is critical to the mobilization flap.
 - The flap is thoroughly undermined and advanced medially for closure of the eyelid defect (**TECH FIG 1C**).

Tarsal Edge Repair and Flap Inset

- The tarsal edges should be incised anew as necessary so they are perfectly perpendicular to the lid margin, sacrificing as little tissue as possible.
 - The tarsal edges are then apposed and sutured with partial-thickness 6-0 polyglactin suture (S-14 spatulated needle) (**TECH FIG 2A**).
- The eyelid margin is repaired using 6-0 silk sutures, which are left long and draped away from the wound awaiting incorporation into subsequent skin sutures.
 - Three sutures are placed along the margin—the first through the gray line, second through the tarsus, and third through the lash line.
 - The suture bites should be equidistant from the wound on each side of the defect, and the vertical excursion of the bite should be longer than the horizontal excursion of the bite to facilitate wound eversion.

- Minor to moderate amount of anterior lamella tension can be relieved with placement of interrupted 6-0 polyglactin sutures through the orbicularis oculi, particularly at the level of the primary lid crease.

TECH FIG 1 • Schematic representation of the Tenzel flap for reconstruction of a lower eyelid defect. **A.** Flap markings. Circular areas shown with *dotted lines* are undermined to elevate flap in the submuscular plane. **B.** Flap markings in a patient with a lower eyelid basal cell cancer. **C.** Flap elevation and transection of the lower crus of the lateral canthal tendon.

TECH FIG 2 • **A.** Suturing the tarsal edges after flap elevation and lateral canthal tendon transection. **B.** Lateral canthal fixation of the flap tissue is performed

to prevent lateral sagging and to minimize tension on the repaired defect.

- The skin is closed with 6-0 nylon sutures.
- The long ends of the lid margin silk sutures are incorporated into the second nylon suture away from the lid margin.
- To prevent lateral sagging and poor opposition of the lower eyelid to the globe and to minimize tension on the repaired defect, the lateral canthal fixation of the flap tissue is performed with placement of 4-0 polyglactin on a semicircular needle to secure the deep surface of the flap to the inner aspect of the superolateral rim periosteum (**TECH FIG 2B**).
- Improved eyelid contour can be obtained by incorporating a lateral orbital rim periosteal flap.
 - The flap is typically 8 to 10 mm wide, and the length is determined by measuring the distance from the rim to the lateral end of the tarsus on the flap.
 - It is hinged at the arcus marginalis, typically based at least midpupil, and angled superiorly 45 degrees to follow the eyelid contour and to provide upward pull on the lid.
 - It is sutured to the lateral tarsal edge of the mobilized flap.

Donor-Site Repair

- The semicircular donor site is closed in layers with 5-0 or 6-0 polyglactin sutures in a buried fashion for the muscles and 6-0 polypropylene sutures for the skin (**TECH FIG 3**).
- An excision of the Burrow triangle or extension of a skin incision may sometimes be necessary to prevent trapdoor deformity.

TECH FIG 3 • A,B. Flap advancement and final closure of the defect and donor site.

■ Posterior Lamellar Flap

- For larger defects or for those without the tarsus at the lateral edge, a posterior lamellar graft may be necessary to provide extra stability.
- Auricular cartilage, hard palate mucosa, nasal septal chondromucosal graft, free tarsoconjunctival graft, allograft, or xenograft can be used after harvesting in the usual manner.
- The tissue should be cut into rectangular fashion to snugly fit into the space between the lateral most tarsal edge and the lateral orbital tubercle.
 - 5-0 polyglactin sutures are used to secure the graft in place on both ends.
- If a periosteal flap or mucosal graft is used laterally, conjunctival advancement is unnecessary.
- Otherwise, the conjunctiva is advanced from the inferior fornix to the superior skin margin of the Tenzel flap, and it is secured with 7-0 chromic gut or polyglactin sutures.

PEARLS AND PITFALLS

Corneal protection	■ Protect the cornea during the procedure with a corneal shield. ■ Complete canthotomy and cantholysis are necessary to ensure sufficient mobilization of flap for wound closure. ■ Lateral canthal fixation is critical to prevent postoperative lid sagging or poor globe apposition. ■ Conjunctival lining of the posterior lamellar graft helps to prevent formation of symblepharon, adhesion of conjunctival/eyeball to the flap.
Hemostasis	■ Meticulous hemostasis is critical.
Dressing	■ Dressing contact lenses are useful in some cases to treat/prevent corneal epitheliopathy.

POSTOPERATIVE CARE

- Topical antibiotic ointment is used three times per day until first postoperative visit at 1 week.
 - Typical ointments are bacitracin ophthalmic preparation or erythromycin ointment.
- The lids may appear tight but will relax overtime with avoidance of manipulation of lid by patients.
 - Nylon and silk sutures are removed 7 to 10 days after repair.
- Temporary upper lid ptosis secondary mechanical dragging of the flap on the lateral upper lid tissue usually resolves after several weeks.

OUTCOMES

- A smooth lid margin resting at the inferior corneal limbus along with upward contour of the lid at the lateral canthus is desirable.
- Erythema along the eyelid margin in the area of the flap fades over time to give more normal appearance except for madarosis (loss of eyelashes).

COMPLICATIONS

- Wound dehiscence may occur with excessive wound tension especially with incomplete lateral canthotomy and cantholysis or when the tissues have been chronically inflamed.
 - Because of the friable nature of a dehisced wound, careful manipulation is required to resuture the already damaged tissue edges.
- Eyelid notching can be avoided by ensuring eversion of wound edges at the margin with silk sutures.

- Ectropion may occur in case without lateral canthal fixation to the orbital rim.

22 Eyelid Reconstruction With the Hughes Flap or Cutler-Beard Flap

CHAPTER

Larissa Habib and Brian Marr

DEFINITION

- The Hughes flap was originally described in 1937 and has been modified to increase efficacy and minimize postoperative complications.
 - It is an effective vertical lid-sharing procedure that can achieve good functional and cosmetic results for lower eyelid greater than 50% defects resulting from trauma or cancer excision.
 - It involves a tarsoconjunctival advancement flap to recreate the lower lid posterior lamella.
 - The anterior lamella is recreated using a full-thickness skin graft or a local skin flap.¹
- The Cutler-Beard flap is a cutaneoconjunctival advancement flap from the lower lid that is used for very large (greater than 70%) defects in the upper eyelid.
 - Indications are tumor resection, trauma, and congenital defects.
 - The goal is to provide lid apposition to protect the eye, good aesthetic quality, and good mobility.²

ANATOMY

- The upper and lower eyelids meet at the medial and lateral canthus with the lateral canthus sitting 2 to 4 mm higher than the medial (**FIG 1**).
- The palpebral fissure is approximately 28 to 30 mm in length and 9 to 10 mm in height.
- The eyelid anatomy can be divided into anterior and posterior lamellae.
- The anterior lamella consists of the skin and the orbicularis oculi muscle.

- The eyelid skin is the thinnest in the body (less than 1 mm). The epidermis receives its nourishment from a deeper connective tissue layer as it lacks blood vessels and lymphatics. There is a sparse amount of fat in the preseptal and preorbital skin, and fat is absent in the pretarsal skin.
- The orbicularis oculi is loosely adherent to the skin and divided into orbital and palpebral portions. The palpebral is further divided into pretarsal and preseptal. The palpebral portion functions in blinking and voluntary winking. The orbital portion is for forced closure.
- The posterior lamella consists of the tarsus and the conjunctiva.
- The tarsal plate is composed of dense fibrous tissue. It is approximately 1 mm thick and provides the structural support of the eyelid. The upper eyelid tarsus extends from the punctum to the lateral canthus and is 30 mm long and 7 to 10 mm high, with the highest portion being centrally. The lower tarsus is only 3.8 mm wide. The ciliary border contains meibomian gland orifices that provide the lipid layer of the tear film. The medial and lateral ends are attached to the orbital rim by the medial and lateral palpebral ligaments.

FIG 1 • A,B. External and sagittal section depicting the eyelid anatomy as well as surrounding structures.

- The conjunctiva is a mucous membrane that covers the sclera and the inner eyelids. The palpebral conjunctiva is adherent to the tarsus and then

continues as the orbital conjunctiva where there is a plane that allows dissection from the Mueller muscle. At the fornix, the conjunctiva reflects anteriorly to become the bulbar conjunctiva.

■ Upper eyelid retractors

- The levator palpebrae superioris arises at the orbital apex and courses anteriorly for 40 mm ending in the aponeurosis 10 mm behind the septum. At this junction, it changes direction to vertical and then inserts inferiorly onto the lower third of the tarsal plate. In addition, some fibers pass anteriorly to form the eyelid crease.

- The Mueller muscle originates from the undersurface of the levator at the muscular aponeurotic junction and then travels between the levator and the conjunctiva to insert on the superior border of the tarsus. It is innervated by the sympathetic nervous system.

■ The lower eyelid retractors are an extension of the inferior rectus muscle.

- They pass anteriorly and envelop the inferior oblique before joining the inferior transverse ligament to become the capsulopalpebral fascia and inserting at the inferior border of the tarsal plate.

- A small portion of the retractors joins with Tenon capsule at the inferior fornix and courses anteriorly to form the lower lid crease.

■ Blood supply is derived from both the internal and external carotid arteries.

- Medially, two palpebral branches (superior and inferior marginal arteries) arise from the ophthalmic to supply the upper and lower lid. These arteries then travel horizontally as the marginal arcades that lie on the tarsal plate (4 mm from the upper margin and 2 mm from the lower margin).

- Laterally, the lacrimal artery provides branches to both the upper and lower lids, which travel horizontally to anastomose with the marginal arcades.

■ The external carotid contributes through branches of the facial, superficial temporal, and infraorbital arteries.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The preoperative evaluation includes a detailed examination of the extent of the lid defect, in particular, the extent of involvement of the anterior and posterior lamellae.

- The adjacent skin, contralateral upper eyelid, postauricular, and supraclavicular areas should be inspected for potential donor skin.

IMAGING

- Preoperative photos should be taken to document the extent of the defect.
- Imaging with CT or MRI can be considered based on etiology of the defect, in particular in trauma situations to assess other injuries or embedded foreign body.

SURGICAL MANAGEMENT

Preoperative Planning

- In determining whether a Hughes procedure is appropriate, one must consider the size and location of the defect as well as the status of the other eye.
 - An alternative procedure may be preferred if there is limited vision in the opposite eye as vision will be temporarily obscured by the vascular flap.
 - The extent of the posterior lamella defect and the anterior lamella defect must be determined to assess the size the flap as well as to determine the donor site for the skin graft.
- The extent of the posterior lamella defect and the anterior lamella defect must be determined to assess the size of the Cutler-Beard flap.
 - It is also important to assess the visual function of the contralateral eye as this procedure requires closure of the eye for up to 3 weeks.

Positioning

- For the Hughes flap, the patient should be supine with the postauricular area and contralateral eye exposed after draping.
- For the Cutler-Beard flap, the patient should be supine with both eyes exposed after draping.

TECHNIQUES

■ Hughes Flap

Flap Creation

- Local anesthetic is injected into the pretarsal upper lid as well as subconjunctivally above the superior tarsal margin.
- The upper eyelid is everted using a Desmarres retractor to gain access to the conjunctiva and tarsal plate.

- A horizontal incision is marked 4 mm from the lash line to match the length of the posterior lamellar defect of the lower lid (**TECH FIG 1A**).
- The tarsus and conjunctiva are incised horizontally, and then the incision is extended vertically from both ends toward the fornix.
- The tarsus and conjunctiva are dissected away from the levator aponeurosis to the level of the Whitnall ligament so that the flap can be pulled downward to cover the defect without too much tension (**TECH FIG 1B**).
- The flap is then advanced to the lower lid and sutured to remnants of tarsus medially or laterally with 5-0 Vicryl on P-2 needle (**TECH FIG 1C,D**).
- To cover the flap and recreate the anterior lamella, an advancement skin flap or free skin graft can be considered depending on the size of the defect as well as the laxity of the skin (**TECH FIG 1E**).

TECH FIG 1 • A. The upper lid is everted on a Desmarres retractor, and an initial incision to match the length of the lower lid defect is made through conjunctiva and tarsus, 4 mm from the lash line. **B.** The tarsoconjunctival flap is dissected away from the

levator and the sutured into place in the defect. **C,D.** The free skin graft sutured over the pedicle flap. **E.** Photograph showing the vascular pedicle in place in the lower lid defect, with the overlying free skin graft.

Separation of Flap

- The flap is separated 4 to 6 weeks postoperatively.
- A muscle hook is used to lift the flap from the conjunctiva, and Westcott scissors are used to separate the graft along the lower lid.
- The conjunctiva is sutured to the lower lid margin using 6-0 chromic gut.
 - The conjunctiva should be slightly higher than the skin surface to protect the cornea and to impart better appearance.
- Mueller muscle and levator aponeurosis are dissected away from the overlying skin and allowed to retract back.

■ Cutler-Beard Flap

Flap Creation

- The lower lid is measured and marked horizontally to match the upper eyelid defect. The mark is extended vertically to the fornix.
 - An attempt should be made to fashion the flap to fit the defect without much modification to preserve as much tissue as possible.
- Local anesthetic is injected into the upper eyelid defect and the pretarsal lower lid as well subconjunctivally.
- A full-thickness horizontal incision with a no. 15 blade is made 4 to 5 mm below the lash line, leaving the lower eyelid margin and tarsus intact.
 - This is important so as to avoid the marginal artery that provides essential blood supply to the remaining lower eyelid.
 - Westcott scissors are then used to extend the incision laterally and medially. The incision is then extending vertically to the fornix (**TECH FIG 2B**).
- The flap is divided into a conjunctivocapsular layer and a superficial skin and orbicularis layer.
- The deeper layer is sutured to the remaining conjunctiva of the upper lid superiorly, medially, and laterally with 7-0 Vicryl (**TECH FIG 2C**).

- The skin and orbicularis layer are then sutured to the margin of the upper lid with interrupted 6-0 chromic gut (**TECH FIG 2D**).

TECH FIG 2 • **A.** Patient with a sebaceous cell carcinoma of the upper eyelid prior to excision. **B.** An incision corresponding to the upper eyelid defect is made through the lower eyelid. **C.** The lower eyelid flap is sutured into the upper eyelid defect. **D.** Patient with Cutler-Beard flap in place.

Separation of Flap

- At 4 to 6 weeks, the flap is separated.
- A muscle hook is used to lift the flap from the conjunctiva and Westcott scissors are used to separate the graft.
- The conjunctiva is cut so that there is an extra 1 to 2 mm for some eversion after it is sutured to the skin. This improves long-term appearance and prevents rubbing of the corneal surface by the skin edge.
- The retracted portion of the lower flap is reattached to the bridged lower eyelid (**TECH FIG 3**).

TECH FIG 3 • Final result after flap separation.

PEARLS AND PITFALLS

HUGHES FLAP

Indication

- Lower lid defects $\geq 50\%$.

Technique

- Ensure 4-mm remaining tarsus in the upper lid. Consider free graft if sufficient anterior lamellae to support it.
- Ensure complete dissection from upper lid retractors to prevent

	postoperative upper lid retraction.
Postoperative care	■ Advise the patient the limitations of temporary monocular vision. ■ At stage 2 or when opening the flap, take care to contour a smooth line with the remaining eyelid margin for a good cosmetic result.
CUTLER-BEARD FLAP	
Indication	■ Upper lid defect greater than 70%.
Technique	■ Horizontal incision 4 mm below lash line to avoid compromise of donor eyelid blood supply. ■ Ensure 1–2 mm of redundant conjunctiva when separating graft to improve appearance. ■ In patients who may need more upper eyelid support, a second procedure can be done using AlloDerm, hard palate, or ear cartilage. ■ If the defect extends medially or laterally, the graft may not be sufficient, and additional revision may be necessary to reform the canthal angle. ■ When dividing the flap, take care to form or align the medial and lateral canthal angles with the divided flap edge.

POSTOPERATIVE CARE

- Antibiotic steroid ointment combination with patch for 48 hours.
 - The ointment should be continued twice a day for a week.
- The graft is separated at 4 to 6 weeks.

OUTCOMES

- In a series of 125 cases using the Hughes flap,³ 15.2% had minor perioperative complications including trichiasis (9.6%), pyogenic granuloma (1.6%), and corneal ulceration (4%).
 - Major perioperative complications included flap necrosis (0.8%) and flap dehiscence (1.6%).
 - Long-term consequences included ocular irritation (16%, 40% resolved at 6 months) and mucous discharge (2.4%).
 - Three cases needed reoperation for trichiasis, ectropion, and lower lid retraction.
 - Patient satisfaction was reported as 88% with appearance and 80% with ocular comfort.

- Most patients do very well after a Cutler-Beard flap, both functionally and cosmetically. There are, to date, no large case series to describe the outcomes.
- In a small case series by Carroll, 3 of 10 patients developed cicatricial entropion after this procedure.⁴

COMPLICATIONS

- Hughes flap
 - Complications can occur in the acute or chronic setting. Acute complications include the following:
 - Flap dehiscence
 - Skin/flap necrosis
 - Trichiasis or abnormal positioning of the eyelashes resulting in growth of the lashes into the eye resulting in irritation. Mild cases can be treated with topical medications until swelling resolves. More severe cases may require ablation of the eyelashes with laser or surgical removal.
 - Chronic complications include the following:
 - Entropion
 - Ectropion
 - Lagophthalmos
 - Upper lid retraction
- Cutler-Beard flap
 - Scarring and retraction of the lower lid
 - Upper eyelid entropion
 - Lid margin irregularity
 - Eyelash loss
 - Bridge flap necrosis
 - Lower eyelid margin necrosis

23 Lower Eyelid Reconstruction With Palatal Grafts

CHAPTER

Farooq Shahzad, Babak J. Mehrara, and Aaron Fay

DEFINITION

- With proper case selection, lower eyelid reconstruction can be enhanced using hard palate grafts.
- Both horizontal deficiency and vertical retraction can be corrected using this technique.
- Palatal grafts are not suitable for upper lid reconstruction because the keratinized surface can abrade the underlying cornea.

ANATOMY

Eyelids

- For purposes of reconstruction, it is useful to consider the eyelids in three constituent layers, or lamellae: anterior, middle, and posterior (**FIG 1**). Below the lid crease in the region of tarsus, only anterior and posterior layers can be defined.
- The anterior lamella comprises skin and orbicularis oculi muscle. Eyelid skin is the thinnest in the body, entirely lacking subcutaneous fat. This makes skin matching difficult when placing full- or split-thickness skin grafts. Whenever possible, eyelid skin grafts are harvested from the contralateral or opposing eyelids.
 - The lashes arise in the anterior lid margin and project anteriorly and superiorly in the upper lid. In the lower lid, the lashes are less robust, projecting anteriorly and inferiorly. Lamellar disjunction can produce eyelash ptosis that interferes with vision.
 - Orbicularis oculi is a thin, circumferential striated muscle that can be

conceptualized in three regions: pretarsal, preseptal, and orbital. Pretarsal orbicularis extends all the way to the lid margin, where it can be visualized as the “gray line” separating anterior and posterior lamellae. This important landmark is known as the muscle of Riolan. Responsible for blinking, the preseptal orbicularis extends from the tarsal periphery (superior edge or inferior edge of tarsus in the upper or lower eyelids, respectively) approximately to the level of arcus marginalis around the orbital rim. When stimulated, this portion of orbicularis produces complete, intentional, mildly forceful closure with no radial rhytide formation, as used, for example, upon sleeping. Preseptal orbicularis stimulation is usually accompanied by a Bell phenomenon (upward rotation of the eyeball). The orbital portion of orbicularis oculi extends peripherally beyond the arcus marginalis and eventually interdigitates with frontalis and corrugator muscle superiorly. This portion of muscle produces tight, forceful eyelid closure accompanied by glabellar and lateral rhytide formation. Orbicularis oculi originates and inserts along the raphe near the medial and lateral canthi.

FIG 1 • A. Sagittal section through superior eyelid showing lamellar anatomy. Below the lid crease, the anterior and posterior lamellae are well defined. Anterior lamella consists of skin and muscle, while posterior lamella consists of tarsus and conjunctiva. Above the lid crease, three layers of lid are recognized: conjunctival and retractor muscles constitute the

posterior layer, orbital fat and septum constitute the “middle lamella,” and skin and muscle constitute the anterior lamella (extension of SMAS onto the eyelid). **B.** Anterior view of eyelids demonstrates the normal contour and resting position of the upper and lower lid margins. Note that the superior limbus and inferior limbus are concealed by the upper and lower lid margins, respectively.

- The middle lamella, distinguishable only superior to the primary upper lid crease (and inferior to the tarsus in the lower eyelid), consists of a fibrous orbital septum and orbital fat. The orbital septum originates at the arcus marginalis along the superior orbital rim and inserts onto the distal aponeurosis of levator palpebrae superioris. This plane defines the anterior limit of the orbit; the skin and orbicularis represent the terminal extension of the frontal SMAS, whereas retroseptal tissues (levator muscle, Muller muscle, and conjunctiva) originate deep within the orbit. These distinctly different planes fuse along the orbital septum, the “periosteum” of the eyelid.
- The posterior lamella consists of the conjunctiva, tarsus below the lid crease, and eyelid retractors above the lid crease. Levator palpebrae superioris (levator muscle) and Muller muscle (sympathetic eyelid muscle) form the upper eyelid retractors. In the lower lid, these muscles fuse more completely, the so-called capsulopalpebral fascia. All structures in the upper lid have analogues in the lower eyelid. Formed of collagen (not cartilage), the tarsal plates are the structural elements of the eyelid, lending rigidity, stability, and directionality especially to the lid margin regions. The center of the upper and lower lid tarsi are approximately 10 and 4 mm high, respectively. These structures taper laterally and medially where they fuse with medial and lateral canthal tendons. Because they taper quite significantly, direct closure of tarsal defects produces mismatched tarsal elements; the lid margin provides a template for reconstruction.
- The medial canthal tendon inserts on the medial orbit via two crura, along the anterior and posterior lacrimal crest. During reconstruction, it is important to reconstitute the posterior crus so that the lid hugs the ocular surface all the way to the caruncle. Without it, the lid can become distracted anteriorly, leaving a space between the lid margin and ocular surface. The lateral canthal tendon

inserts on the periorbita of the lateral orbital tubercle of Whitnall posterior to arcus marginalis. Here again, it is important to reattach the tendon posteriorly in order to draw the lid tightly against the globe all the way to the commissure, particularly in deep-set eyes and, less importantly, in relatively proptotic eyes.

- Upper eyelid contour forms a smooth, continuous arc with its apogee typically at the medial pupil. The upper eyelid margin typically conceals 2 mm of superior cornea, whereas the lower lid sits at or just above the inferior corneal limbus. These measures should be evaluated with the patient's head in neutral position, as chin-up or chin-down positioning will dramatically alter the lower lid position. Simultaneous unveiling of the superior and inferior limbus produces a "Walt Disney eye," characteristic of thyroid eye disease. An imaginary line segment connecting the medial and lateral canthi is slightly canted upward and outward in most patients, the positive canthal tilt. During reconstruction, the lateral canthus should be placed approximately 2 mm superior to a horizontal line drawn through the two medial canthi.
- The blood supply to the eyelid forms anastomoses between internal and external carotid artery circulations through the marginal and peripheral vascular eyelid arcades extending across the eyelids. The external carotid circulation progresses medially through the facial artery and then the angular artery and laterally through branches of the superficial temporal artery. Supraorbital, supratrochlear, and infraorbital branches from the ophthalmic artery form the internal carotid contribution.

Hard Palate

- The hard palate separates the oral and nasal cavities. The anterior three-fourths is formed from the horizontal process of the maxilla, whereas the posterior portion consists of horizontal portion of the palatine bone. The anterior and lateral periphery of the palate is known as the alveolar arch. Posteriorly, the hard palate is continuous with the soft palate.
- The mucosa of the hard palate is tightly bound to the periosteum by a surprisingly thick fibrous submucosa. The midline mucosal ridge is called the palatine raphe (**FIG 2**).
- The blood supply of the hard palate is via the greater palatine artery that exits the greater palatine foramen medial to the 3rd molar. This vessel travels anteromedially and enters the incisive foramen in the anterior palate. The greater palatine nerve travels with the artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

■ History

- Historical visual acuity is obtained to help determine visual potential in the eye. History of dry eye or other ocular pathologies should be obtained, with ophthalmic consultation as indicated.
- The etiology of the defect and the need for any further treatments (eg, radiation, foreign bodies, residual or recurrent malignancy, thyroid disease, anticipated intraocular surgery) are noted.
- A history of previous eyelid surgeries or radiation may affect the type of reconstruction.

FIG 2 • Palatal anatomy.

- A history of previous palatal surgery is obtained. History of cleft palate is a relative contraindication.
- Physical examination
 - Ophthalmic examination should include visual acuity, extraocular muscle

function, presence or absence of Bell phenomenon, and eyelid function.

- A defect analysis is performed, looking at the following elements: anterior and posterior lamella, medial and lateral canthal tendons, and the lacrimal apparatus. Lacrimal involvement in the defect should prompt further evaluation with likely simultaneous lacrimal reconstruction.
- The eyelid and periorbital tissues are assessed for suitability for use in reconstruction. Pre-existing surgical scars and tissue laxity is noted.
- The palate is examined to ensure its adequacy as a donor site.

SURGICAL MANAGEMENT

- Hard palate grafts are useful primarily for reconstructing defects in the posterior lamella of the lower eyelid. Because the graft contains thick fibrous tissue as well as mucous membrane, it can be used to replace tarsus as well as conjunctiva. Only tarsoconjunctival grafts and flaps can provide this benefit, but they are in rare supply and often not available. However, because hard palate mucosa is keratinized, it can damage the cornea in the early phase before metaplasia to a nonkeratinized mucosa can take place.
- Because it is a free graft, the hard palate segment must be conjoined with an advancement or rotational myocutaneous flap or a temporary or permanent pedicle of muscle or fascia (eg, Mustarde).
- The hard palate graft can insert into a full-thickness defect to replace the horizontal length of the tarsus or in vertical continuity with the tarsus to correct eyelid retraction (more common).

Preoperative Planning

- Grafts require a healthy bed of vascularized tissue to survive. For isolated posterior lamellar defects, the graft can be placed on the intact anterior lamellar orbicularis muscle.
- If the eyelid defect is full thickness, anterior lamellar reconstruction needs to be performed with a vascularized flap.
 - Commonly used local flaps for upper eyelid anterior lamellar reconstruction include local orbicularis transposition or rotation, Tenzel semicircular, Fricke temporal transposition, glabellar transposition, and forehead flaps.
 - Commonly used local flaps for lower eyelid anterior lamellar reconstruction are local orbicularis advancement or rotation flaps, Tenzel semicircular flap, upper eyelid myocutaneous transposition flap (unipedicled [Fricke] or bipedicled [Tripiet]), nasolabial transposition flap, Imre rotation flap, and

Mustarde cheek rotation flap.

- A sandwich technique can also be used where the orbicularis muscle is used as a bed for anterior and posterior lamellar grafts. The orbicularis has a robust blood supply and can be mobilized into the defect. A skin graft is placed on its anterior surface and a posterior lamellar graft on its bulbar surface.

Positioning

- The operation is performed in the supine position.
- A shoulder roll extends the neck and facilitates visualization of the hard palate.
- Exposure of the palate is obtained with a Dingman mouth gag. Alternatively, a side-biting mouth gag and tongue retractor can be used.
- A lubricated corneal shield is used to protect the eye during surgery.
- The instruments for eyelid surgery and palatal graft harvest should be kept separately to minimize contamination of the eyelid wound with oral secretions.
- Gloves should also be changed when going from the mouth to the eyes to minimize infection.

TECHNIQUES

■ Harvest of Hard Palate Graft

- The dimensions of the posterior lamellar defect requiring the palatal graft are noted.
 - A template of the defect made with a piece of rubber glove or sterile packaging can be very helpful.
- Markings are performed with methylene blue. Surface landmarks are marked to help with orientation.
 - The posterior edge of the hard palate and the palatal midline are marked.
 - The greater palatine vessel is palpated medial to the 3rd molar. Its location is marked with a dot.
- The graft can be harvested between the midline, the posterior edge of the hard palate, and the marginal gingiva. The greater palatine vessel is to be avoided.
 - The palatal mucosal thickness increases with increased distance from the marginal gingiva.¹ Staying at least 3 to 4 mm anterior to the posterior edge

of the hard palate and toward the midline will prevent inadvertent injury to the soft palate and the greater palatine neurovascular bundle (**TECH FIG 1A**).

- The template is positioned on the palate at the optimal location for harvesting.
- The graft is marked a few millimeters larger than the defect to account for the minor graft contraction that occurs during the first few postoperative months.²
- Local anesthetic consisting of bupivacaine with epinephrine is infiltrated into the mucosa.
 - The needle should not be pushed in up to the palatal bone as this will hydrodissect the periosteum off the bone.
- The hard palate incisions are made with a no. 15 blade.
 - Care is taken not to inadvertently push the knife against the palatal bone and thus incise the periosteum.
- The graft is then elevated in the submucosal plane using an angled beaver blade, Freer periosteal elevator (in the submucosal plane), and curved Stevens scissors (**TECH FIG 1B**).

TECH FIG 1 • Palatal graft harvest. **A.** The palate is marked close to the midline raphe in order to avoid the palatal artery and nerves. **B.** Harvest site can be dressed with processed cellulose fabric to help maintain hemostasis. **C.** Harvested graft can be trimmed to appropriate thickness to match recipient site tarsus and conjunctiva.

- The hard palate graft is stored on the back table in an antibiotic solution (**TECH FIG 1C**).
- Hemostasis is ensured with a bipolar electrocautery.
- If the greater palatine vessel is inadvertently injured, it may need to be tied off.
- Surgicel can be sutured onto the raw palatal surface. It controls the minor oozing from the wound and also covers the surface to decrease postoperative pain from irritation of the wound.

■ Inset of Hard Palate Graft for Posterior Lamellar Reconstruction

- The graft is inspected. If it is too thick, it is trimmed to appropriate thickness.
 - Any visible mucous glands on the posterior surface of the graft are excised.
- The graft is inset with its mucosal surface directed posteriorly.
- It is sutured to the margins of the posterior lamellar defect (ie, laterally to the remaining medial and lateral tarsal plates and inferiorly or superiorly to the tarsal remnant or the conjunctiva using 7-0 polyglactin sutures; **TECH FIG 2**).
- Suture knots are placed on the deep side of graft away from the ocular surface.
- Lateral canthal anchoring is performed if there is any pull on the eyelids or for lax eyelids.
 - Failure to do so in high-risk patients will result in postoperative ectropion.
- A bandage contact lens can be placed for corneal protection. This is especially useful in reconstruction of upper lid posterior lamella.
- A traction suture can be used to suspend the lower eyelid in cases of reconstruction of large posterior lamellar defects or when the graft is used as a spacer for reconstruction of severe lower lid retraction.
 - The suture is removed after 1 week.

TECH FIG 2 • Hard palate graft in recipient bed, in this case, used to augment lower tarsus for correction of lid retraction.

PEARLS AND PITFALLS

Graft harvest

- The posterior extent of graft harvest should be 3–4 mm anterior to the posterior edge of the hard palate and toward the midline. This is to prevent inadvertent harvest of soft palate mucosa, which can result in a palatal fistula or injury to the greater palatine vessels.
- A template of the defect aids in marking the graft at an optimal location on the palate. It should be marked a few millimeters larger to account for the minor graft contraction that occurs during the first few months postoperatively.

Corneal protection

- The cornea is protected during the procedure with a corneal shield. Postoperative corneal epitheliopathy can be prevented with a dressing contact lens, particularly in upper eyelid reconstruction.

Hemostasis

- At the end of the procedure, hemostasis must be obtained. The palatal donor site can also be covered by Surgicel cellulose fabric, which can decrease bleeding and sensitivity of the open wound.

Lateral canthal anchoring

- There should be a low threshold for lateral canthal anchoring in eyelid reconstruction. Eyelid laxity is usually managed by correctly sizing the interpositional graft but should be addressed at the time of reconstruction.

POSTOPERATIVE CARE

- Oral antibiotics can be used for 24 to 72 hours as needed.
- Oral hygiene is emphasized. Chlorhexidine gluconate 0.12% squish and spit after meals and at bedtime is used for 7 to 10 days.
- Topical lidocaine jelly can be used for pain control.
- In patients with severe postoperative discomfort, an obturator can be placed over the donor site to cover the open wound from irritation while it is healing.

COMPLICATIONS

- The hard palate donor site reconstitutes the mucosa over several weeks. The

time to heal increases with the size of the wound.

- Delayed healing can occur, usually due to infection.
- Bleeding is the most frequent complication of hard palate graft harvest, reported in up to 10% of patients.³
 - If local pressure does not control bleeding, electrocautery or suture ligation is required.
- Additional complications include keratin debris at the recipient site in the early postoperative period⁴, eyelid or palatal infection, palatal fistula, partial graft dehiscence, and graft failure.
- Late complications include lower lid retraction, ectropion, entropion, and corneal injury.

24 Lateral Tarsal Strip Canthoplasty

CHAPTER

Richard H. Caesar

DEFINITION

- Any lower eyelid laxity or frank ectropion of the lower eyelid that results in a failure of the lower eyelid to sit smoothly against the globe can lead to symptoms of epiphora, discomfort, and poor appearance.
- Lower eyelid tightening is a crucial component of the treatment of lower eyelid ectropion of any cause.
- Any entropion of the lower eyelid (inversion of the lower eyelid) will usually have lower eyelid laxity as a component of the etiology. Lateral tarsal strip can be used to address this laxity with additional steps to reattach the lower eyelid retractors.
- Lateral tarsal strip canthoplasty is a powerful technique for lower eyelid tightening.¹

ANATOMY

- The lateral canthal tendon attaches the lateral ends of the tarsi to Whitnall tubercle, 2 mm posterior to the lateral orbital rim formed by the zygomatic bone.
- It is the origin of the palpebral and pretarsal orbicularis muscle fibers that pass to the medial canthal tendon.

PATHOGENESIS

- Common causes of acquired ectropion include age-related laxity and cicatricial changes resulting from iatrogenic causes, trauma, or burns.
- A paralytic ectropion results from a loss of innervation to the orbicularis muscle and facial elevators.

- Mechanical ectropions are rare and result from external forces such as eyelid tumors.

NATURAL HISTORY

- Acquired ectropion in most cases can only be corrected with surgery.
- Notable exceptions are temporary paralytic ectropion that can have full spontaneous recovery and mild cicatricial ectropion secondary to dry skin or dermatitis. Intensive treatment with emollients, anti-inflammatory agents, and massage can, on occasion, fully resolve the ectropion.
- Acquired entropion (lower eyelid inversion with abrading of the conjunctiva/cornea by the eyelashes) always requires surgery for a permanent solution.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Notable patient history and physical findings that should be assessed include appearance, epiphora, and pain/discomfort.
- Lower eyelid laxity with marginal eversion and conjunctival exposure should be assessed.
- Also assess secondary inflammation and thickening of the eyelid margin.
- Exclude tethering or cicatricial changes of the skin, lower eyelid retractors, or conjunctiva. Exclude mechanical cause and paralytic cause.

IMAGING

- Imaging is not usually required, but orbital MRI may be useful to identify the cause of unusual cicatricial changes to the lower eyelid retractors.

NONOPERATIVE MANAGEMENT

- Surgery may be avoided with a resolving paralytic ectropion and a treatable mild cicatricial ectropion.
- If the patient does not want surgery or is unable to have surgery, the eye can be kept comfortable by means of intensive ocular lubricants day and night. We recommend preservative-free hyaluronic acid-based lubricants during the day and white soft paraffin at night.
- Involutional entropion can be treated with injection of botulinum toxin to the lower orbicularis.²

SURGICAL MANAGEMENT

- Lower eyelid laxity and frank entropion and ectropion repair requires lower

eyelid tightening. This can be achieved by many different techniques to include wedge resection, skin-sparing wedge resection, lateral canthopexy and lateral tarsal strip.

- Concurrent lower eyelid blepharoplasty, skin grafting, heteropalpebral flap, medial retractor repair, central retractor repair, and surgery to the medial canthal tendon may also be required.
- The lateral tarsal strip remains one of the most powerful techniques to tighten the lower eyelid.

Preoperative Planning

- The surgeon should define the position of the incision, the degree of eyelid shortening required, and the angle of placement of the deep suture to the orbital rim.
- Concurrent additional procedures should be determined.
- The vast majority of patients are comfortable with local anesthesia alone, but sedation and general anesthesia should be available when required.

Positioning

- The patient is most comfortable lying reasonably flat with a cushion under the head and knees.
 - The surgery can be done with the patient sitting if required.
- The surgeon sits to the side of the patient.

TECHNIQUES

■ Markings and Anesthesia

- Mark the incision from the lateral canthal angle to extend 10 to 12 mm laterally and inferiorly following the most obvious rhytide (**TECH FIG 1A**).
- Mark the extent of the tarsal strip required.
- Mark the angle of fixation to the posterior orbital rim by following the curve of the lower eyelid.
- Instill local anesthetic drops (oxybuprocaine or tetracaine) to the conjunctival fornix.
- Injecting local anesthetic (**TECH FIG 1B**), 2 mL of 2% lidocaine with 1:200 000 epinephrine, superior and inferior to the lateral canthus, is effective and avoids the marginal arcades.
- Clean with povidone-iodine and drape the surgical field.

TECH FIG 1 • **A.** Mark the skin with the incision, the extent of the tarsal strip, and the position to suture to the rim. **B.** Inject local anesthetic at the lateral canthus superior and inferior to the marginal arcades.

■ Removing the Tarsal Strip

- With a no. 15 blade, make a primary skin incision, and then perform a lateral canthotomy and dissect to the orbital rim with blunt-tipped Westcott scissors (**TECH FIG 2A**).
- Expose the orbital rim with blunt dissection.
- Grasp the exposed lateral edge of the tarsal plate with toothed forceps and use the scissors to make a pocket anterior to the tarsal plate, between the

tarsus and the orbicularis.

- Cut along the inferior border of the tarsal plate to release the conjunctiva and septum.
- Release the anterior lamella along the gray line to the preplaced mark of the extent of the strip.
- Remove the superior eyelid margin in a thin strip with the scissors (**TECH FIG 2B**).
- Excise any redundant anterior lamella as a small triangle.
- Remove the conjunctiva over the inner, posterior aspect of the tarsal plate with bipolar cautery (**TECH FIG 2C**). Compress the tarsus to release the meibomian contents.
- Trim off the most lateral portion of the tarsus to reveal the fully stripped lateral tarsus.

TECH FIG 2 • **A.** Incise the skin and use blunt-tipped Westcott scissors to perform a canthotomy to the orbital rim. **B.** Use the scissors to create the tarsal strip. **C.** Use cautery to remove the conjunctiva from the inner aspect of the tarsal strip.

■ Placing the Tarsal Strip

- Use a double-armed 5-0 Prolene suture or double-armed 5-0 Vicryl or equivalent (**TECH FIG 3A**).³
- First, pass the suture through the tarsus from superior to inferior, perpendicular to the eyelid margin.
- Then, pass one arm of the suture from posterior to anterior at the inferior border of the tarsal strip. Pass the second arm from posterior to anterior at the superior border of the strip.
 - The suture passed from posterior to anterior will place the strip in the best anatomical position on the inner aspect of the orbital rim once tied.
- Pass the superior suture through the periosteum at the orbital rim. This is most easily achieved by placing the suture on the rim, passing it backward until the tip trips inside the rim, and then passing forward to catch the periosteum on the inner aspect of the orbital rim.
- Check the eyelid and canthal position. Adjust the vertical position of the suture to the orbital rim if incorrect.
- Place the second inferior suture 2 mm lower on the orbital rim (**TECH FIG 3B**).
- If using 5-0 Prolene, tie five knots with the needles still attached. Then, bury the end of the suture by passing the needle posteriorly and laterally from the knot to exit (**TECH FIG 3C**). Trim at exit.
- If using 5-0 Vicryl, tie and cut as normal.
- Close the orbicularis with a deep 6-0 Vicryl suture if required.
- Close the lateral canthus and skin with two or three interrupted 6-0 Vicryl sutures (**TECH FIG 3D**).

TECH FIG 3 • **A.** Pass a double-armed suture posteriorly to anteriorly through the tarsal strip. **B.** Anchor the suture to the inner aspect of the orbital rim. **C.** Bury the ends of the suture. **D.** Close the angle and skin with interrupted sutures.

PEARLS AND PITFALLS

Granuloma formation	■ Discharge the contents of the meibomian glands within the tarsal strip.
Bruising	■ Avoid the marginal arcades when injecting local anesthesia and maintaining meticulous hemostasis.
Irritation from deep suture	■ Knot with needles attached and use the needle to pass the end of the suture flat and posteriorly.
Asymmetry	■ Careful preop marking and intraoperative adjustment of suture placement to the orbital rim.
Pulling the lower lid inferiorly on the globe	■ Beware negative vector patients with prominent eyes.

POSTOPERATIVE CARE

- Topical antibiotic ointment is applied daily to the eye and the sutures until sutures are removed or dissolve.
- Ice packs are used for the first 24 to 48 hours to reduce inflammation.

OUTCOMES

- Tarsal strip canthoplasty results in high patient satisfaction with effective outcomes in 87% to 96% of patients.^{4,5}

COMPLICATIONS

- Infection
- Chemosis
- Bruising
- Visible scar
- Asymmetry
- Suture granuloma
- Prolonged tenderness over deep suture

Section VIII: Cheek

25 Cheek Reconstruction With Laterally or Medially Based Cervicofacial Flap

CHAPTER

Sammy Sinno and Barry M. Zide

DEFINITION

- Local tissue from the cheek and upper neck provide the best tissue for cheek reconstruction; several techniques have been described including submental and sternocleidomastoid flaps.^{1,2}
- Laterally, or posteriorly, based cervicofacial flaps are most useful for small to moderate full-thickness skin and subcutaneous defects of the anterior and inferior cheek. These flaps take advantage of the loose neck skin to provide a large amount of coverage with local/regional tissue borrowed from the lateral face, neck, and even chest. Laterally based flaps avoid incisions below the eyelid; however, crossing the anterior mandibular border may require a Z-plasty (**FIG 1**).
- Medially, or anteriorly, based cervicofacial flaps are also useful for moderate sized full-thickness skin and subcutaneous defects of the anterior and upper cheek. These flaps also take advantage of the loose preauricular and neck skin and avoid incisions on the mandible.

FIG 1 • Lateral-based and medial-based cheek flaps.

ANATOMY

- The cheek is a laminated structure consisting of skin, subcutaneous tissue, and the superficial musculoaponeurotic system (SMAS). These structures overlie the facial nerve, parotid gland, buccal fat pad, and mandible.
- The arterial supply to the cheek is provided by the facial, superficial temporal, and transverse facial arteries originating from the external carotid artery. Venous drainage may parallel the arterial system though variations are common (**FIG 2**).
- Techniques of deep-plane elevation or tissue expansion can be used to improve the blood supply and reliability of the flap.²⁻⁵
- The cheek can be subdivided into overlapping zones to categorize lesions and organize the reconstructive strategy (**FIG 3**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The cheeks are often exposed to trauma and sun damage leading to a frequent requirement for reconstruction.

FIG 2 • Arterial blood supply of the cheek.

FIG 3 • The three reconstructive zones of the cheek. Red border between zones 1 and 2 marks a vertical line dropped from the midpupil. Zone 1, lateral cheek; zone 2, central cheek; zone 3, inferomedial cheek. Laterally (posteriorly) based cheek flaps work best for zone 3 defects. Medially (anteriorly) based flaps are best for zone 1 and 2 defects.

- The defect size, depth, and location must be evaluated in addition to the surrounding skin quality, tone, and texture.
- Hairlines should also be noted, particularly sideburns in women, as this will affect flap design due to the need to avoid hair transposition onto the cheek.
- Patients should be encouraged to stop smoking as this increases the risk of distal flap necrosis.
- For skin cancer defects, consider delaying the reconstruction until the

resection margins are proven clear by histological analysis.

- The effect of radiation therapy must also be taken into account when applicable.
- Ensure that the blood supply to the face is intact by evaluating neck and facial scars.
- Specifically evaluate the area where the facial and superficial temporal arteries are located. Pay particular attention to prior sentinel lymph node biopsy scars in the face and cheek.

IMAGING

- No imaging is required other than that indicated by a preoperative clearance workup.

SURGICAL MANAGEMENT

Preoperative Planning

- Smaller cervicofacial flaps may be performed under local anesthesia or deeper anesthetic techniques.
- Assess the mobility and laxity of the skin surrounding the defect and determine which facial structures may be distorted by flap movement.
- Scars should be positioned at the border of aesthetic units (nasal-facial junction, nasolabial fold, infraorbital rim) or along the hairline when possible, which may require sacrifice of additional tissue.
- If it is not possible to place the scar at the border of aesthetic units, scars should be aligned parallel to relaxed skin tension lines (these are curvilinear on the cheek).

Positioning

- Patient is positioned supine on the operative table with the head turned to the contralateral side from the defect.
- The ipsilateral face, neck, and chest are prepped into the field. Alternatively, the entire face may be prepped into the field to assess symmetry intraoperatively.

Approach

- Depending on the size and location of the defect, decisions must be made regarding plane of flap elevation (subcutaneous or sub-SMAS), extent of

posterior incision (preauricular, postauricular, chest), and need for preoperative tissue expansion.

- If the surgeon decides to go sub-SMAS, it is critical to spread obliquely so the nerves stay on the downside.
- The senior author rarely performs sub-SMAS dissection for posteriorly based flaps.
- Incisions should follow the nasolabial fold and can continue to the submental crease.
- Larger defects may require an incision that extends posteriorly toward the sternocleidomastoid muscle.
- Patients (especially nonsmokers) with smaller defects and significant skin laxity that allows for defect closure under minimal tension are good candidates for cervicofacial flaps elevated in the subcutaneous plane.
- Large defects, poor skin laxity/quality, and a positive smoking history are additional indications for tissue expansion or deep-plane elevation of the cervicofacial flap to minimize the risk of distal flap necrosis.
- Deeper defects may also benefit from deep-plane elevation (including the platysma muscle in the neck) as the greater flap tissue bulk prevents contour depression over the defect that may be seen with only skin and subcutaneous tissue coverage.

TECHNIQUES

■ Laterally Based Cervicofacial Flap

- The defect is outlined, and flap is drawn to place scars along the borders of aesthetic subunits (**TECH FIG 1A**).
- After completion of the flap design, dilute 0.5% lidocaine with 1:200 000 epinephrine is infiltrated in the subcutaneous plane.
- Using sharp and blunt dissection, the entire flap is elevated in a subcutaneous plane (**TECH FIG 1B**).
- Support of the flap may be required, and anchors, periosteal sutures, and sutures around the medial canthal tendon can aid greatly.
- After obtaining hemostasis, the flap inset begins anteriorly with buried deep dermal 5-0 PDS suture and rotating the flap superiorly and anteriorly.

- Working anteriorly, each advancement point is secured with buried deep dermal 5-0 PDS suture.
- Excision of any dog ear at this point is crucial. When the scar crosses the mandibular border, a Z-plasty or W-plasty is often required below the mandible.
- Scar placement should rest without excess tensions along the nasolabial fold.
- A drain is placed.
- The skin incision is closed with running and interrupted 6-0 Prolene sutures.

TECH FIG 1 • A. The defect is outlined, and the flap is marked. Note the incision along the nasolabial fold with, in this case, a posterior back cut. The inferior incision should be “cut as you go.” **B.** Flap elevation in the subcutaneous plane. Note that a deep plane can be used if there are concerns for flap ischemia.

■ Medially Based Cervicofacial Flap

Creating the Flap

- Similar to the laterally based flaps, the cheek defect is outlined and drawn to place scars along the borders of aesthetic subunits (**TECH FIG 2A**).
- The flap markings begin at the superior and lateral edge of the defect and, if possible, can be placed at the junction between the cheek and eyelid. In some

cases (**TECH FIG 2B**), the excision includes the lower eyelid skin in which case the flap incision is placed within the lower eyelid itself.

- It should be remembered, however, that the closer the incision is to the lid margin, the higher the risk of ectropion.
- The marking of the lateral portion of the apex of the flap is placed approximately 1 cm superior to the lateral canthus. This helps to suspend the cheek flap above the lateral canthus, thus decreasing the risk of ectropion.
- The flap edges are infiltrated with a dilute solution lidocaine with epinephrine as outlined above.
- Skin incisions are performed and the skin flap is elevated in the subcutaneous plane.
 - Care must be taken to avoid raising excessively thin flaps as this increases the risk of flap necrosis.
 - Similarly, care must be taken to avoid injury to the facial nerve with excessively deep dissections.
- The flap may be elevated using a no. 10 blade or with a fine-tipped electrocautery (eg, Colorado needle) at a low setting (15).
 - The dissection continues medially until the defect is reached.
 - The medial and inferior borders of the defect are similarly elevated in the subcutaneous plane.
- Flap dissection is then continued inferiorly down to the neck, taking care to avoid injury to the great auricular nerve over the sternocleidomastoid muscle (**TECH FIG 2C**).
- The extent of the dissection depends on the patient's skin laxity and the amount of excess skin in the neck. This can be judged by periodically gently pulling the skin flap over and analyzing the tension on the flap.
- Meticulous hemostasis is achieved with bipolar electrocautery.

Insetting the Flap

- Once adequate dissection has been performed, a back cut on the flap is performed to decrease tension on it.

TECH FIG 2 • A. Melanoma in situ with 0.2-mm deep lesion in center. The wound is dressed after getting clear margins on step sections. The flap is elevated in the sub-SMAS plane with oblique spreading of scissors to avoid nerve injury. The flap design: the incision goes straight back or up slightly the distance of the width of the lesion removed. It then moves to the mid tragus and downward to the lobule. The incision goes straight back about 3.5 cm and an angle opened 60 to 70 degrees is marked in **B**. The incisions are well hidden and the sub-SMAS dissection guarantees reliability not found in the Mustarde-type flap. **C.** Final result.

- The patient's face/neck is then placed in the extreme lateral position to maximize the length of flap that is necessary to close the wound with no tension. Temporary sutures are placed in the superolateral portion of the defect (ie, the area that is at greatest tension) to the flap minimizing tension on the flap as much as possible.
- The remainder of the flap is inset with temporary sutures again aiming to minimize tension on the flap.
 - Particular attention should be placed in the preauricular area as closure of the flap defect at this area can result in excessive tension on the flap. If this is the case, a small triangular area in front the ear can be left open and skin grafted with a full-thickness graft harvested from the excess portions of the flap.
- The inferomedial portion of the flap usually has a small dog-ear from the flap rotation.
 - Excision of this dog-ear is marked in such a way to avoid narrowing of the flap base (**TECH FIG 3**).
 - In some cases, a secondary revision may be necessary.

TECH FIG 3 • Dog-ear excision in the inferomedial portion of the flap. Note angulation of the dog-ear to avoid narrowing of the flap base (*arrow*).

PEARLS AND PITFALLS

Incision placement

- Incisions should be placed along borders of facial aesthetic units whenever possible. This may require excision of additional tissue surrounding the defect.
- Avoid vertical incisions in the central cheek anterior to a line dropped down from the lateral canthus (Z-line).
- Dog-ears do not settle down no matter how long you look at them. The flap should be completely flat at the time of surgery. If flap viability may be jeopardized, tell the patient about the potential residual dog-ear before the first stage.
- Excise dog-ears in a manner that does not narrow the flap base.

Flap choice

- Laterally based cervicofacial skin flaps survive better than medially based flaps because the transverse branches of the facial and superficial temporal arteries are preserved.

Skin cancer

- Consider delaying the reconstruction until the margins of resection are proven clear by histological analysis.

Flap suspension

- Larger defects require longer incisions with wider elevation and undermining. Larger flaps frequently have tension at the cheek closure that may compromise blood supply and are vulnerable to flap ptosis.
- Suspend to the medial canthal tendon if required.
- Leave dog-ears if necessary.

Flap readvancement

- Similar to other rotational flaps, these may be readvanced for serial excisions, positive margins, or partial flap loss.

POSTOPERATIVE CARE

- Patients should rest with their head elevated for the first few days postoperatively.
- Skin sutures should be removed 5 to 10 days postoperatively.

- Large flaps with wide undermining extending onto the inferior neck may require placement of a closed suction drain.
- Postoperative antibiotic coverage is not necessary.

OUTCOMES

- Laterally and medially based cervicofacial flaps provide excellent color and texture match with the ability to camouflage scars in the cheek borders.
 - Proper patient selection, appropriate flap design, gentle tissue handling, and hemostasis minimize complication rates (**FIGS 4 and 5**).
- Two major drawbacks to cervicofacial flaps include unpredictable distal tip perfusion and anterior skin excess requiring excision as a vertical dog-ear.
 - Incidence of distal tip necrosis has been reported in 14.5% of cases; this is reduced with sub-SMAS elevation.⁶

COMPLICATIONS

- As noted, distal tip necrosis is a problem. However, the incidence of this complication can be minimized by avoiding tension on the flap, elevation of the flap in a thick subcutaneous or, in some cases, submuscular plane, and meticulous attention to hemostasis.
- Contour deformities, dog-ears, and scarring can occur particularly in large, deep defects. These may require revision surgery such as scar revision, dog-ear excision, or resurfacing.
- Hematomas occur commonly after facelifts and cheek flaps due to the excellent blood supply of the face. Meticulous hemostasis is therefore necessary.
 - In addition, if general anesthesia is used, it is important to have a calm emergence and avoidance of hypertension during extubation.
- Infection is rare but can occur and should be treated aggressively.
- Facial nerve injury is also rare but can occur in thin patients or in cases where submuscular dissection is performed.

FIG 4 • A. The melanoma just under 1 mm is removed full thickness. The anterior margin is moved to the nasojugal fold and along the nasolabial fold. The Schrudde designed flap is lifted sub smas preserving nerves by oblique spreading of scissors. The flap design goes straight back the width of the lesion and the distance to the nasojugal fold and then down to mid tragus. A 70-degree flap is designed under the ear. After closure, the ear lobule is left to auto tube to preserve correct lobule shape. **B.** The final result is well supported. The flap design does not require the usual upswing of the flap behind the defect as the Schrudde design already does this. The ear lobule has auto tubed.

FIG 5 • A. Preoperative image of patient who underwent

laterally based cervicofacial flap. Immediate **(B)** and 12-month **(C)** postoperative views.

26 Cheek Reconstruction With Tissue Expanders

CHAPTER

John T. Stranix and Barry M. Zide

DEFINITION

- Tissue expansion is a proven technique for generating additional cutaneous tissue to reconstruct facial defects when local coverage options are otherwise inadequate.
- Skin adjacent to, or near, the surgical defect is stretched over time to produce adequate local tissue of similar color and texture for coverage without creation of a donor-site defect.
- Expansion is achieved through placement of a buried prosthesis that is gradually filled with saline via a distant port.
- As the volume of saline increases, the prosthesis enlarges and stretches the overlying tissue to cause expansion.

ANATOMY

- Skin expansion results from mechanical stress applied over time through both mechanical creep (cellular stretch) and biologic creep (increased cellular proliferation).
- Thickening of the epidermis occurs with concurrent thinning of the dermis and alignment of collagen fibrils.
- Angiogenesis occurs in response to ischemia generated by tissue expansion, increasing both the number and caliber of blood vessels in the expanded tissue. This is similar to the increased vascularity seen with the delay phenomenon and expanded flaps can be considered delayed flaps.
- Skin of the anterolateral neck shares essentially the same color, texture, and dermal appendages as the skin covering the majority of the cheek. This excellent match makes the neck an ideal donor site for cheek reconstruction

with tissue expansion.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Tissue expansion is performed over 3 to 4 months, requiring office visits 5 to 7 days apart. This requires a motivated, well-informed, and compliant patient and family. Sometimes, twice-weekly fills can expedite expansion.
- In some cases, parents and/or patients can do the fillings with proper instruction.
- Tissue expansion has a higher complication rate in children compared to adults.¹ Smokers also have an increased risk of complications.²
- Facial tissue expansion must take into account the location, size, shape, and type of defect (nevus, burn, trauma, oncologic).
- Expansion under scars or radiated tissue should not be done.
- Consideration should be given to the aesthetic subunits involved, adjacent specialized structures that may be disrupted/distorted, skin quality, pre-existing scars, and any additional areas with reconstructive needs.
- Available donor sites for expansion must be evaluated as this will determine the size and type of expander possible.

SURGICAL MANAGEMENT

- The increased vascularity of expanded lateral cheek and neck tissue enables the design of unique advancement, rotation, or transposition flaps specific to individual cheek defects.
- There are three general approaches to tissue expansion for coverage of cheek lesions:
 - Expansion of tissue immediately adjacent to the defect (which thins the skin)
 - Cervicofacial flap expansion and/or neck expansion for cervicofacial flap donor-site coverage
 - Direct expansion from below the lesion to allow excision and primary closure
- An expander placed in the upper neck (as opposed to an expander placed immediately adjacent to the defect) is preferred because this approach results in decreased skin thinning.
- Transillumination of the expander in situ is a helpful technique because this approach identifies the major blood vessels of the flap by enabling the surgeon to perform back cuts more accurately.
- The Schröder angle rotation flap adapts well to an expander placed in the

neck. This flap incorporates an angular subcutaneous flap below the ear and backward. When the flap is brought up and forward, it fills the area in front of the ear, which would have a defect otherwise.

- The size of the required expander can be calculated directly based on the length and width of the expected defect. When using a single expander, the length of the expander should be equal to or greater than the longest side of the lesion. The width of the expander should be the maximum possible according to anatomy.
- The timing required to reach full expansion and the amount of fluid needed for expansion vary based on the quality and quantity of skin. Similarly, the timing of transfer after adequate fill has been obtained varies based on the condition of the skin and the amount of expansion that has been done. However, in general, once full expansion has been obtained, the transfer can be safely scheduled after 1 to 2 weeks.

Preoperative Planning

- Careful flap planning should incorporate the expander placement incision(s) and align scars with borders of aesthetic units when feasible.
- For large expanders, multiple access incisions may be required to allow for adequate expander pocket dissection. Incisions are usually preauricular or open V shaped in the scalp or along the Schröder infra-auricular incision.
- If re-expansion and readvancement may be required for serial excisions, this should also be incorporated into flap choice and design. Serial expansions and excisions are associated with a higher extrusion rate during subsequent expansions.³ The author rarely re-expands the face.
- Actual or anticipated defect size must be determined to select the appropriate number, size, and orientation of tissue expander(s). Location of remote port placement should be distant from the expander and secured in situ.
- Donor-site selection plays an important role with the goal of providing a good soft tissue match in color, texture, and contour. For cheek reconstruction, the lateral cheek and neck provide an excellent match.

Positioning

- The procedure can be performed under sedation with monitored anesthesia care or full general anesthesia with the patient positioned supine on the operative table.
- The head is turned toward the contralateral side from the defect, and the

ipsilateral face, neck, and chest are prepped into the field.

- Administration of an antibiotic with skin flora coverage 30 to 60 minutes prior to incision is recommended.

Approach

- Size, shape, and number of the expanders
 - As stated earlier, in cases in which a single expander is used, the length of the expander should be longer than the length of the incision required to replace the intended area, whereas the width of the expander should be roughly equal to the width of the expected defect. In practice, we use the widest expander possible based on anatomic constraints.
 - Using the largest expander possible within the limitations of donor-site anatomy will reduce the number of expanders (and total expansion) required.
 - Compared to the expander base area, expander volume is less important due to the minimal risk of hyperinflation up to 10 times above the manufacturer's stated nominal capacity.⁴
 - Using multiple expanders allows more rapid expansion with fewer complications than single expanders and should be considered when feasible.²
 - Soft, flat, rectangular silicone expanders with rounded corners are recommended for expansion of head and neck tissue. In the face and neck, floppy bag expanders are avoided due to knuckling and extrusion problems.
- Port placement
 - Remote filling ports are preferred in the head and neck over integrated filling valves and are typically placed in the postauricular scalp or neck.
 - External filling valves may be helpful in children, but the port egress site must be dependent to allow for periprosthetic fluid drainage and should be far from the expander (greater than 6 cm) as they are associated with a higher infection risk.⁵
 - Ports must be secured to prevent drift.
- Incision placement
 - Incisions for expander placement should not interfere with subsequent flap advancement or compromise the blood supply to the expanded tissue. Ideally, placement incisions are either incorporated into the subsequent flap design (like the Schrudde infra-auricular V), placed within the area to be excised, or distant like the scalp.
 - Access incisions should be kept away from the expansion process (greater

than 2–3 cm) and never oriented parallel to expander edges as this increases exposure risk. Incisions should be either perpendicular to the expander or in the shape of a V or W with the broad base directed toward the expander.

■ Flap incisions and tissue transposition

■ Simply cutting around the advancing edge of the expander base does not take full advantage of the expanded tissue.

■ The following flap designs enable the most efficient use of expanded local tissue for coverage:

- The single back-cut flap is ideal for triangular defects. The single back cut allows the flap to be advanced and/or transposed and is a workhorse technique. The flap can be shaped or contoured in a way to recreate a side burn or exactly tailored to a defect.
- The double back-cut flap provides maximal gain of soft tissue advancement and is best for round or rectangular lesions. These flaps are amenable to re-expansion for serial excisions.
- Over-the-top advancement flap allows for simple calculation of the amount of soft tissue available in the flap. This type of advancement is used when the expander was larger than the square-shaped defect. It does require sacrifice of some adjacent normal tissue over the lateral edges of the expander, and the required dog-ear excisions cause the flap to narrow when advanced.

■ Expanded cervicofacial flap

■ A powerful technique for coverage of large cheek defects (greater than 3 cm) incorporates tissue expansion into the design of cervicofacial rotation/advancement flaps.

■ Benefits of cervicofacial flap expansion include the following:

- Improved flap vascularity, which may obviate the need for sub-SMAS flap elevation
- Allows coverage high onto the temporal area and farther medially and inferiorly
- Facilitates tension-free closure
- Transillumination demonstrates axial blood supply, enabling utilization of the maximal flap back cut to optimize rotation/advancement
- Remote expander placement away from the defect reduces exposure risk, with access incisions directly incorporated into flap design.

■ Direct expansion and closure

- For nonexpansile lesions of the cheek, direct expansion from underneath the defect itself enables excision and primary closure.
- This technique minimizes the degree of undermining necessary and has the benefit of resulting in a straight line scar that can be favorably oriented along resting skin tension lines.

TECHNIQUES

■ Tissue Expander Insertion

- Once the flap design and implant position are determined, mark out the access incision, remote port location, and planned expander pocket.
- Infiltrate a dilute solution of 1:200,000 to 1:400,000 epinephrine in a subcutaneous plane throughout the marked areas.
- After a period of 7 to 12 minutes for vasoconstriction, make the access incision (usually 2–3 cm long) into subcutaneous tissue.
- Develop the expander pocket with a combination of blunt and sharp dissection in the subcutaneous plane staying above the superficial musculoaponeurotic muscular system (cheek) and platysma (neck).
- Make sure the pocket is far enough away from the incision so the expander is about 2 cm from the access point.
- With the same technique, create a superficial pocket for the remote fill port that is separate from the expander pocket but accessible through the same incision.
- Hemostasis should be checked and the pocket should be irrigated.
- Prior to insertion, trim the port tubing to the appropriate length to avoid redundancy that may lead to kinking and check the expander for leaks.
- After rolling and inserting the expander into the pocket, attach a 16-gauge plastic angiocath to the expander tubing, completely deflate the expander, and then clamp the tube.
- The connector is placed and tied with two 3-0 Tevdek or Ethibond sutures on each side to prevent detachment. The port is also secured so it does not drift. The tubing to the expander must be on the down side.
- Make sure the skin overlying the port is loose and the tubing does not kink.
- When you are satisfied with port position and palpability, place a suture

around the tubing but under the skin adjacent to the dome to secure the port in place.

- The port tubing must be sutured in place to prevent drift into the larger pocket.
- Place a small closed suction drain that is tunneled to a separate, remote stab incision for egress.
- Use a 23-gauge needle to transcutaneously access the port and partially fill the expander with injectable saline (about 10% volume). This initial fill unfurls the expander, obliterates dead space caused by undermining the pocket, and allows assessment of the connection between the port and expander.
- Check to make sure the insertion of the port tubing into the expander is on the downside.
- Make sure the expander lies flat in the pocket after the partial fill by pushing on the overlying skin—no edges should be felt. If the pocket needs adjustment, pull out the expander first, or else, it may be cut in the procedure.
- Once adequate expander position is obtained, close the access incision(s) in layers.

■ Expanded Flap Elevation and Inset

- Following adequate expansion, design a flap that will provide defect coverage and draw it in marker over the expanded tissue (**TECH FIG 1A,B**).
- When designing the back cut, transilluminate the flap to identify and mark the location of axial blood vessels (**TECH FIG 1C**).
 - Division of these should be avoided and will determine the maximal extent of your back cut.
- Infiltrate a dilute solution of 1:2-400 000 epinephrine in a subcutaneous plane throughout the marked areas.
- Perform the marked incisions through the dermis.
- Using cautery, elevate the flap in a subcutaneous plane until the expander capsule is encountered.
- Cautery will not cut the expander and thus avoids a flood of saline into the field.
- Incise the expander capsule the entire length of the incision.
- Additional capsulotomy and subcutaneous undermining of this proximal

tissue should be performed as needed for adequate movement.

- Although the capsule edge may be removed if it prevents motion, significant capsulectomy should not be performed as this may compromise flap blood supply.
- If excessive tension is present, the back cuts may be extended up to the first axial vessels encountered on transillumination to provide additional rotation.
- Rotate and inset the flap (**TECH FIG 1D,E**).
- Place a small closed suction drain that is tunneled to a separate, remote stab incision for egress (can use the same stab incision previously used with expander placement).

TECH FIG 1 • **A,B.** Markings for a Schrudde design flap wherein a triangle placed under the ear allows the flap to move without worry of needing to fill the defect from flap movement. The flap should not go right under the eyelid unless the lid is supported by fascial slings. **C.** The expanded flap is transilluminated so the back cuts do not interrupt blood supply. With the lights out in the OR, the vessels are easily visible. **D.** The flap should be supported by sutures to periosteum or fascia, indicated by *arrows*. **E.** Completed flap inset.

■ Expanded Cervicofacial Flap

- Refer to the chapter Cheek Reconstruction With the Angle Rotation Flap for flap design. The flap is designed in exactly the same manner, except expansion is performed prior to elevation and advancement.

- Expansion of the cervicofacial flap is usually done with a neck expander and may avoid sub-SMAS flap elevation.
- A subcutaneous implant pocket is designed 1 cm larger in all dimensions. Expander insertion is performed through the preauricular flap incision, which may be extended cranially to facilitate exposure. A submental counterincision may also be helpful for pocket dissection.
- The remote fill port can be placed in the scalp or behind the ear.
- Perform the incisions and expander removal in the same manner as the subcutaneous flaps above.
- Additional subcutaneous dissection should be performed for complete flap elevation. Flap advancement, inset, and superomedial support should be performed according to the techniques detailed in the chapter Cheek Reconstruction with the Angle Rotation Flap.
- Take full advantage of the improved vascularity and quantity of soft tissue. Align planned incisions with aesthetic subunit borders, sacrificing some residual normal tissue from the medial cheek if necessary (**TECH FIG 2**).
- There is usually a vertical dog-ear medially that requires excision.
- In addition to the cutaneous inset of the above flaps, these larger flaps require suspension from periosteum, bone anchors, and temporal fascia.

TECH FIG 2 • A. An OR fire burned this woman. The graft to the lower eyelid was too small, the cheek had an expander attempt, and it became exposed. The red line indicates the delay incisions made at the time of expansion placement. The green line shows the incision for the final flap. **B.** Flap inset.

■ Neck Expansion for Donor-Site Coverage of Large Cervicofacial Flaps

- For larger cheek defects, deep-plane cervicofacial flap elevation may be performed in conjunction with neck soft tissue expansion for donor-site coverage (**TECH FIG 3A,B**).
 - This provides the maximum possible flap vascularity by combining the sub-SMAS elevation with tissue expansion delay phenomenon and enables primary donor-site closure with pliable neck tissue.
- The tissue expander is placed in the subcutaneous (preplatysmal) plane inferior to the mandibular border using the above technique (**TECH FIG 3C**).
- Following adequate neck tissue expansion, the cervicofacial flap is designed with transillumination used to identify axial vessel location and incorporate them into the backcut limitations.
- Removal of edge of expander scars and proper back cut will maximize the gain.

TECH FIG 3 • A large AVM extending from the superomedial cheek to the superior ear required excision down to deep temporal fascia. **A.** The flap (indicated in yellow) will go thinly under the lid, as shown by the *green arrow*. **B.** The AVM will be removed to deep temporal fascia. The ear will be reduced. The upper brow will be supported by anchors (*arrows*) as the frontal branches are removed. **C.** Flap design. The neck expander was placed via a preauricular incision to provide additional soft tissue and allow primary donor-site closure for the deep-plane angle rotation cervicofacial flap.

Incisions	■ Keep placement incisions at least 2–3 cm away from the expansion process. ■ Inverted V incisions work well for insertion and allow for expansion to begin at 10 d; must be kept away from base of the proposed flaps. ■ Use back cuts with transillumination to maximize tissue gain and avoid flap devascularization.
Expander selection	■ Rectangular expanders are preferred because you can figure out mathematically when the expander is close to ready. ■ Choose size according to base length dimensions that are slightly larger than the defect (not according to expander volume, as they can be significantly overinflated). ■ Avoid hard-backed, floppy bag, or integrated fill port expanders on the face and neck. ■ Multiple expanders may allow for more rapid expansion but also increase the chance of problems. Expanders, if multiple, should be chosen according to the shape/extent of the defect and what each expander will accomplish.
Expander placement	■ Infiltrate semitumescent dilute epinephrine prior to pocket formation. ■ Make sure the expander lies flat in the pocket after insertion, no edges should be palpable, and the port connection must be on the downside. ■ Make sure the remote port is loose in its pocket, or the overlying skin will necrose, and always secure the port in place. ■ Use a closed suction drain that egresses from a distant site.
Tissue expansion	■ Avoid trying to predict exactly how long expansion takes since this is highly variable. ■ In certain instances, teach appropriate family members to do the expansions at home. ■ Expand until you have approximately 20% more tissue than needed to cover the defect when possible.
Implant exposure/infection	■ Consider temporary deflation, drain any periprosthetic fluid, and start antibiotics if evidence of infection. ■ May save a seemingly infected implant. Drainage from the most dependent portion of the expander and Betadine irrigations can save the day... sometimes. ■ If almost fully expanded, try to incorporate the area of exposure into the back cut of the flap.

POSTOPERATIVE CARE

- Postoperative antibiotics are not required, and the drain is removed within 24 to 48 hours.
- Filling begins at the first postsurgical visit, typically at 7 to 10 days.
- If the expander was inserted through an incision that may be affected by the expansion, it will be necessary to delay filling for 3 weeks.
- Filling should be performed after sterilizing the skin over the port to prevent contamination.
- It is important to use a 23-gauge or smaller needle to prevent port leakage (although the companies say it will work with a 21-gauge needle). A butterfly needle is particularly useful as it allows for slight patient movement without dislodging.
- In children, it may be helpful to apply a topical local anesthetic 20 minutes prior to each filling session.
- Subsequent filling amounts vary but are usually about 5% of the nominal expander volume with intervals between fillings ranging from 4 days to 1 week.
- The expander should be compressible to 1 cm after filling.
- Frequent small-volume inflations are better tolerated, approximately every 5 days.
- When guardians or significant others can be trained or designated as fillers, they can usually fill every 5 days.
- Expansion is complete when the cutaneous tissue generated is able to cover a surface area approximately 20% greater than the defect itself to accommodate for primary flap contraction after expander removal.

OUTCOMES

- Follow-up patient photos are shown in **FIG 1**.

FIG 1 • A,B. Follow-up photos of the patient in TECH FIG 1. She will need additional work for the epicanthal fold, residual nevus on lip, and tightness around the commissure. **C.** Follow-up photo of the patient in TECH FIG 2. The lower lid position is excellent as a graft was used under the margin of the lid. The flap would be too heavy without support. The commissure was repaired later. **D.** Follow-up photo of the patient in TECH FIG 3. The anchor scar is indicated by an *arrow*.

COMPLICATIONS

- Complication rates with tissue expansion vary widely and are directly related to the experience of the individual surgeon.⁶
- Most complications that occur with tissue expansion are technique specific and do not interfere with completion of the planned multistage procedures.²
- Late infections are usually related to iatrogenic contamination during the course of inflation. These infections should be managed with port externalization, irrigation, and antibiotic therapy. Late infections may be salvaged with immediate intervention and antibiotic therapy.
- Implant exposure usually occurs through necrosis of the overlying skin, trauma, a dehiscence and malpositioned incision, or a fold in the implant. Inadequate pocket dissection or too rapid inflation can lead to implant extrusion as well.
- Major complications are rare but include the following:
 - Infection
 - Implant exposure
 - Flap ischemia and/or necrosis
 - Hematoma
- Minor
 - Transient pain with expansion
 - Seroma
 - Widening of scars
 - Dog-ears at donor site

27 Cheek Reconstruction With Free Radial Forearm Flap

CHAPTER

John G. Fernandez

DEFINITION

- Cheek and face defects commonly occur secondary to trauma, burns, or tumor resection.
- Most cheek defects can be treated with primary closure, skin grafts, or local flaps.¹
- Less commonly, reconstruction of cheek defects requires free flap transfer. These defects are more complex, often involve a large area of the skin, or are composite defects involving the cheek skin and underlying tissues.
 - Free flap coverage is necessary owing to lack of local tissues from previous surgery or radiation.²
 - Some patients require free tissue transfer because the facial vessels are ligated during the course of concomitant neck dissection.
 - The radial forearm flap (RFF) is an excellent option in these situations due to its long pedicle, thin and pliable skin paddle, and the potential to transfer multiple skin paddles to line composite through-and-through cheek defects.
- Other flaps are also useful for cheek defects. These include the anterolateral thigh flap, scapular and parascapular flaps, lateral arm flap, fibula flap, and the rectus abdominis flap.
 - Flap selection is based on multiple factors including volume of tissue loss and subsequent functional and aesthetic reconstruction needs.
 - This process is individualized for the patient and the defect to be reconstructed.
- No clear evidence supports one flap over the use of another.
 - The flap must appropriately match the color and thickness of the surrounding

cheek soft tissue and have a reliable blood supply with adequate vessel diameter and length.

- The advantage of RFF is its flexibility in design and its ability to be fashioned as a fasciocutaneous flap, as an osteocutaneous flap involving unicortical short segment of radius, or as composite flaps, including palmaris longus tendon (for lip reconstruction), as well as its ability to be de-epithelialized and folded to reconstruct the intraoral lining and external skin defects.²

ANATOMY

- The borders of the cheek include laterally the preauricular crease, medially the nasal-cheek junction, nasolabial fold and lip, inferiorly the lower border of the mandible, and superiorly the orbital-cheek junction (**FIG 1A**).¹
- The main arterial supply to the cheek is from branches of the external carotid artery with the greatest contribution arising from the facial artery.
- The branches of the facial nerve lie deep to the SMAS.
- The RFF venous drainage is primarily from the venae comitantes, secondary drainage from the cephalic vein (**FIG 1B**).³
- RFF dominant arterial supply is the radial artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history should identify patient factors that may increase the risk of complications, including smoking history, hypertension, obesity, diabetes, and prior radiation therapy.
- Elicit personal or family history of clotting abnormalities, strokes, coronary artery disease, or cerebrovascular disease.
- A personal or family history of clotting abnormalities may warrant a hematology consult to rule out familial causes of hypercoagulability or bleeding diathesis.
- A directed physical examination of the head and neck includes a detailed assessment of the tumor or traumatic defect; nodal involvement; quality of the surrounding cheek skin including laxity, scars, and fine wrinkles; and assessment of facial nerve function.
- Preoperative plan for resection should be determined in consultation with the oncologic surgeons.
- Orbital-cheek junction and periorbital reconstruction may result in eye-related complications including ectropion, scleral show, dry eye, and chemosis.⁴

Therefore, a preoperative and postoperative visual field exam and periorbital assessment may be necessary for lesions that encroach on the eyelid.

- The preoperative evaluation for patients who will undergo cheek reconstruction with an RFF flap includes gathering pertinent patient history such as hand dominance, prior upper extremity surgery, history of trauma, or fractures.
- Consider the body habitus and thickness of the donor tissue and its potential effect on the overall aesthetic and functional outcome.
- An Allen test should be performed to assess ulnar and radial artery perfusion to the hand. Motor and sensory examination of the hand should be performed.
- Patients should be instructed to avoid blood draws or intravenous line placement in the arm to be used for RFF harvest.

IMAGING

- X-ray of the forearm and hand is indicated if an osteocutaneous flap is planned.

FIG 1 • A. Outlines of the zones of the cheek. Note overlap of zones. **B.** Arterial and venous anatomy of the forearm.

SURGICAL MANAGEMENT

- The goal of surgical management is to re-establish the normal anatomy of the face; provide stable soft tissue coverage; allow for normal speech and swallowing, thereby improving quality of life; and maximize aesthetics.
- An RFF is an excellent option for complex defects of the cheek and can be performed to provide external coverage or as a folded flap to repair through-and-through cheek defects.

Preoperative Planning

- Consider the size of the anticipated defect of the aesthetic subunit (suborbital, preauricular, and buccomandibular) and intraoral component (if any).
- Maxillectomy defects often result in periorbital skin defects, whereas mandibulectomies and buccal tumors often include the buccomandibular

subunit.

- Isolated tumors of the buccal mucosa or advanced/recurrent parotid gland tumors may also result in through-and-through defects.
- Melanomas involving the cheek, particularly desmoplastic melanomas, may result in large skin defects in combination with a unilateral neck dissection thereby limiting the potential for reconstruction using local flaps (eg, cervicofacial flap).
- A free RFF is a good option in these circumstances.
- Consider the reconstructive needs and goals to help decide the proper reconstructive technique.
- Perform an Allen test again in the preoperative holding room or operating room to confirm clinic findings. For most accurate results, use a pulse oximeter on the thumb while occluding the radial artery.
- Make sure no blood draws or IV lines are placed in the nondominant arm (use of limb alert bracelet is helpful).

Positioning

- The patient is placed supine on the operating room table with the arm extended 90 degrees on a hand table.
- The head of bed is turned 180 degrees and centered under the lights.
- All pressure points are inspected and protected, and preoperative antibiotics are given within 60 minutes of the incision.
- Corneal eye protectors and sequential compression devices are placed bilaterally.
- Alternatively, the eyelids can be sutured together after application of ointment using a fine nylon suture that is removed after the operation.
- The arm is prepped circumferentially to the level of the axilla. A sterile tourniquet is padded and inflated when the flap is ready to be harvested.

Approach

- The flap is raised under tourniquet control in a distal to proximal fashion.
- It can be raised either subfascial or suprafascial.
- If the fascia is included in the flap, care is taken to preserve the paratenon on the tendons to ensure skin graft take.
- The flap can safely be raised on the superficial venous system, the deep system,³ or both.

TECHNIQUES

■ Flap Design

- Evaluate the specimen and design the flap based on the postablative oral mucosa and/or skin defect measurements (**TECH FIG 1A**).
- Mark the radial artery, cephalic vein, palmaris longus tendon, and FCR.
- Design skin paddle centered over the radial artery and cephalic vein.
 - If a small flap is needed, the cephalic vein can be excluded from the initial design and the flap is centered over the radial vessels. In these cases, it is helpful to incise the distal aspect of the flap first and ensure that the vena comitans of the radial artery is of adequate size for microsurgical anastomosis (**TECH FIG 1B**).

TECH FIG 1 • **A.** Evaluate the specimen and design the flap based on the postablative oral mucosa and/or

skin defect measurements. **B.** Design skin paddle centered over the radial artery and cephalic vein.

■ Flap Dissection

- Elevate the extremity and inflate the tourniquet.
- The flap is incised circumferentially.
 - When making the distal incision, care must be taken to avoid injury to the radial nerve branches as they are superficial in the distal region of the wrist.
 - Similarly, injury to the cephalic vein should be avoided when making the proximal incision (**TECH FIG 2**).
- Subfascial dissection is the safest approach to the flap vessels and can be performed expeditiously. However, care must be taken to avoid injury to the superficial radial nerve.
 - The simplest way to avoid this problem is to identify the radial nerve trunk as it exits below the brachioradialis muscle.
 - The branches can then be traced distally and dissected out of the flap.
 - Small branches entering the skin flap are sharply transected.

TECH FIG 2 • Incision is made with a 10 blade. Incise fascia with knife and raise edges using Adson forceps. Spread with hemostat in the direction parallel to nerves.

■ Subfascial Dissection

- The radial artery and vena comitans are identified distally and ligated.
- The radial vessels are dissected in a subfascial plane from distal to proximal, taking care to avoid injury to the skin-perforating vessels.
 - Small perforators to the muscles and radial bone are cauterized or suture ligated (**TECH FIG 3A**).
- Follow the pedicle as it dives under the brachioradialis tendon (**TECH FIG 3B**).
- Move back and forth between radial and ulnar sides to ensure circumferential view of the radial artery.
 - As you move proximally, use a blunt retractor like a Weitlaner to spread the brachioradialis and FCR (**TECH FIG 3C**).
- Dissect the cephalic vein proximally for additional venous outflow as necessary.
- Incise proximal skin last and be sure to dissect on top of the cephalic vein.
- Mark pedicle orientation with methylene blue or a marking pen.
- Deflate tourniquet and use bipolar cautery for hemostasis.
- Allow the flap to reperfuse for 20 to 30 minutes prior to harvesting for inset and microanastomosis.
- Donor site is closed with skin graft.

TECH FIG 3 • A. In subfascial plane, dissect with knife from distal to proximal. Using the no. 10 blade pointed away from the flap, dissect in subfascial plane staying on the sensory branches of the radial nerve. **B.** Spread under the pedicle perpendicular to the pedicle and bipolar cauterize the tissue. There are multiple perforating branches from the pedicle to the underlying muscle and bone. These small vessels are easily cauterized with a bipolar. **C.** Incise proximal skin last, and be sure to dissect on top of the cephalic vein. As you move proximally, use a blunt retractor to spread the brachioradialis and FCR. This maneuver exposes the radial artery and VC.

■ Flap Inset

- Divide flap pedicle to start ischemia time.
- Transfer flap to the defect and tunnel pedicle vessels to the neck.
- Inset flap at key points to set the pedicle length.
 - If a through-and-through defect is present, then inset the intraoral component first with absorbable sutures (eg, Vicryl) (**TECH FIG 4A**).
- De-epithelialize folded portion of flap with a no. 10 blade.

TECH FIG 4 • A. Transfer flap to the defect and inset flap with an absorbable suture such as 2-0 Vicryl interrupted sutures for the intraoral lining. De-epithelialize folded portion of flap with a no. 10 blade. Inset external skin to flap skin with 4-0 Vicryl for the dermis and 6-0 nylon for the skin. **B.** Vein anastomosis with a coupler device or hand sewn with 10-0 nylon. **C.** Arterial anastomosis is performed with

interrupted 9-0 nylon circumferentially.

- Microsurgical anastomosis is then performed.
 - The recipient arteries most commonly used in the neck are the facial, superior thyroid, or lingual artery, and the recipient veins are the internal jugular or branches of the internal jugular and the facial vein (**TECH FIG 4B,C**).
- The neck and wounds are irrigated with warm saline or antibiotic solution, and hemostasis is ensured.
- A neck drain is placed if necessary.
 - Care should be taken to avoid compression of the pedicle with the drain. This can be done by simply sewing the drain loosely to the sternocleidomastoid muscle.
- The neck skin and platysma, as well as the cheek skin, are closed in a layered fashion.

PEARLS AND PITFALLS

Indications	■ Free flap reconstruction is indicated for through-and-through cheek defects, requiring intraoral lining and external skin coverage. Free flaps are also useful for large defects of the cheek that cannot be closed with local options or skin grafts.
Flap selection	■ No evidence supports one flap over another flap. The flap must match tissue thickness and color and have a reliable blood supply and vascular pedicle.
Postoperative monitoring	■ Free flap survival for head and neck reconstruction is greater than 95%. Frequent clinical observation and Doppler checks are essential for early detection of compromised vascular flow.
Donor site	■ Volar resting splint and negative pressure therapy to skin graft for 5 days. Subsequently, Ace wrap and arm elevation for 3–6 weeks.

POSTOPERATIVE CARE

- The most important factor in flap salvage is thorough monitoring and early detection of compromised vascular flow.

- Clinical observation to assess skin color, temperature, and capillary refill and Doppler sonography are extremely effective in flap monitoring.
- Flap monitoring is performed most frequently in the first 6 hours after surgery (eg, every 1 hour) and gradually decreases over time (Q2 hours × 4 hours; Q4 hours × 48 hours).
- Postoperative antibiotics are generally not necessary and are used for a short duration (5 days).
 - A preoperative dose of antibiotics within 60 minutes of incision has been shown to reduce surgical site infections.
- Deep venous thrombosis prophylaxis includes early mobilization, bilateral sequential compression devices, and subcutaneous Lovenox daily.

OUTCOMES

- The free RFF is a highly reliable flap, able to be folded for intraoral lining and external skin coverage.
- Free flap success rates in head and neck reconstruction is higher than 95%.

COMPLICATIONS

- Donor site wound breakdown or skin graft breakdown leading to tendon exposure
- Poor donor site cosmetic outcome
- If bone is harvested, risk of fracture and potential functional loss
- Ischemic hand
- Partial or total flap loss
- Intraoral leak or fistula
- Infection

28 Cheek Reconstruction With Skin Grafts

CHAPTER

Farooq Shahzad and Babak J. Mehrara

DEFINITION

- The cheeks are the largest aesthetic unit of the face.
 - The boundaries of the cheek are medially the nasofacial groove and nasolabial fold, inferiorly the mandibular border, laterally the preauricular crease, and superiorly the infraorbital rim and the line joining the lateral canthus to the helical root.
- The cheek is subdivided into three aesthetic subunits: suborbital, preauricular, and buccomandibular (**FIG 1**).¹
 - These subdivisions are useful for planning reconstruction.

ANATOMY

- The face has an abundant blood supply with a rich collateral network. The arterial supply to the cheek is via branches of the external carotid artery. The principal supply is via three sources (**FIG 2**):
 - Facial artery and its continuation, the angular artery
 - Transverse facial artery, which is a branch of the superficial temporal artery
 - Infraorbital artery, which is a branch of the internal maxillary artery
- The veins accompany the arteries.

FIG 1 • Aesthetic subunits of the cheek: (1) suborbital; (2) preauricular; (3) buccomandibular.

- The lymphatics of the cheek drain to the parotid, submandibular, and submental nodes. Additional drainage occurs to the jugular nodes.
- Sensory innervation to the cheek is via three sources:
 - Maxillary division (V_1) of the trigeminal nerve via the infraorbital and zygomaticofacial nerves
 - Mandibular division (V_3) of the trigeminal nerves via the buccal, mental, and auriculotemporal nerves
 - Cervical plexus (C_2 , C_3) via the greater auricular and transverse cervical nerves

PATIENT HISTORY AND PHYSICAL FINDINGS

- Cheek defects occur most frequently following skin cancer resection but may also occur after trauma or other causes.

- Skin cancers on the cheek can be removed by conventional methods or using Mohs micrographic surgery.
- Assessment of margins is important and should be discussed with the patient.
- If margin status is in doubt, it is often more prudent to proceed with reconstruction only when the final pathology is reviewed and negative margins are assured.
- Many skin cancer excisions or traumatic injuries of the cheek may be repaired primarily. In other cases, local flap reconstruction or skin grafts are more appropriate.
- Skin grafts are useful in patients with significant comorbidities in whom facial flaps may be contraindicated, situations in which the blood supply to local flaps has been compromised, large defects that are not amenable to reconstruction with local tissues, or cases in which local flap closure may result in distortion of the adjacent structures such as the eyelid or nose.
- For example, skin grafts may be useful in young patients with large superficial cheek skin defects. These patients have tight skin without much redundancy, and thus, attempts to reconstruct larger defects with local flaps will cause distortion of contour or pull on adjacent structures like eyelids.
- Skin grafts are also helpful in some cases for men because facial flaps in these patients may change the distribution of hair growth resulting in a noticeable and difficult-to-treat problem.
- Infrequently, skin grafts may be useful for reconstruction of aggressive or recurrent tumors in which there is a high risk of local recurrence that is more suitable for applying skin grafts to facilitate surveillance.
- Finally, skin grafts may be used in combination with flap closures to extend the reach or avoid tension on the base of the flap or to provide coverage for adjoining anatomic regions (eg, eyelid).

FIG 2 • A. Arterial and venous anatomy of the cheek. **B.** Sensory and motor nerve anatomy of the face.

- The defect is analyzed for the following:
 - Location, size, and depth of the defect
 - Involvement of deeper structures (eg, facial nerve, parotid duct, and oral

mucosa)

- Proximity of the defect to lower eyelid, nasal ala, and lip
- Previous radiation and radiation changes. Heavily radiated or compromised wounds may not be amenable to local flaps or skin grafts and may require vascularized tissue transfer depending on the exposed structures and complexity of the wound.

NONOPERATIVE MANAGEMENT

- Areas of the face with a concave surface heal well with secondary intention healing.
- The cheek is convex, and therefore, secondary healing results in aesthetically displeasing results.
- Exceptions are small preauricular defects and very small medial defects at the alar groove that heal well with local wound care.

SURGICAL MANAGEMENT

- Patient selection for skin graft reconstruction is as discussed above.
- Full-thickness skin grafts taken from within the face and neck (cranial to the clavicles) will have better color and texture match.
 - Common donor sites are the preauricular or postauricular areas, neck, upper eyelid, and supraclavicular region.
- Scars are ideally placed at the borders of the cheek.
 - In general, however, subunit principle and excision of normal skin are not necessary or advised. In rare circumstances, the margins of the graft may be adjusted to blend into normal anatomic structures (eg, nasolabial fold or lower eyelid-cheek margin).

Preoperative Planning

- The condition of the wound bed is examined. Contaminated wounds or those with eschars will need debridement and dressing changes until an appropriate bed is available for skin grafting.
- If possible, skin grafting should be delayed until the wound has granulated enough to decrease contour deformities that may result from deep excisions. In practice, this is not always possible, however, because of contracture and deformity of adjacent structures.
 - One potential solution is the use of decellularized dermis or other material (eg, Integra) to promote wound filling and granulation, thereby avoiding

contour deformities.

- Anticoagulants or antiplatelet agents may be discontinued or bridged prior to the procedure; however, the risk of stopping these medications (eg, stroke, MI) should be weighed against skin graft loss and should be individualized.
- In most cases, consultation with the patient's primary care or medical team is needed to make this decision.
- The expected postoperative course should be discussed with the patient.
- Full-thickness skin grafts initially turn pale and then become hyperemic as they revascularize. They stay pink for several weeks before settling down to their final color. Often, these grafts initially look pin cushioned and fibrotic but soften up over a period of 2 to 3 months. These issues are minimized with optimization of the recipient bed and preservation of the full thickness of the dermis (and even a small amount of subcutaneous layer).
- Possible future revision procedures should also be discussed if necessary.

Positioning

- Patient is positioned supine, with the head at the edge of the bed.
- Small transparent dressings (Tegaderm) are used to tape the eyes closed for protection.
- Preoperative antibiotics are administered.

Approach

- Skin graft reconstruction of cheek defects can be performed with a full-thickness or split-thickness skin graft.
- Full-thickness skin grafts are generally preferred for the face as they have better color, texture, and thickness match. They cause less secondary contracture and are preferable if the defect is close to structures like eyelids or lips.
- Split-thickness skin grafts have a better take and may be needed for reconstruction of larger defects.

TECHNIQUES

■ Cheek Reconstruction With Full-Thickness Skin

Graft

- The procedure can be performed under general or local anesthesia, depending on size of the wound, general medical condition, and patient preference.
 - Nerve blocks can enhance patient comfort.
 - The cheek can be anesthetized by injecting the infraorbital, zygomaticofacial, and mandibular branch of trigeminal (V₃) nerves.²
- The entire face and neck are prepped with a povidone-iodine solution and draped.
 - This wide exposure allows visualization of both sides of the face to check for symmetry and gives access to all donor sites.
- The wound bed is prepared.
 - If there is fibrinous material in the wound, it is cleaned down to healthy tissue (**TECH FIG 1A**). One simple way of doing this is by rubbing a dry piece of gauze in the wound, which will remove loose fibrinous material and nonviable debris.
 - A water-based device (eg, Versajet) can be used for more aggressive yet controlled debridement. For thick eschars (eg, burn wounds), a scalpel or Weck blade is used.
- A template of the defect is made with a sterile glove wrapper. An easy way to do this is to press the wrapper against the wound. The blood will stain the wrapper and outline the defect. This can then be cut with scissors and tailored to the shape of the defect.
- An appropriate donor site is then chosen. Donor sites within the face and neck have a better color match compared to more distal sites.
- The template is oriented on the donor site and marked (**TECH FIG 1B**).
 - Local anesthetic (0.25% bupivacaine with epinephrine) is infiltrated.
- The skin graft is harvested full thickness using a knife.
- The donor site is closed. Undermining of the edges can be done to help the closure.
- The skin graft is defatted on the back table.
 - This is performed by stretching out the graft using hemostats at four edges of the graft and placing of the nondominant finger.
 - A very thin layer of fat may be left in select cases with optimum recipient beds and can improve outcomes. This thin fat layer supports gliding of the

graft and may enable future revision with fat grafts to correct contour deformities if they arise.

- Care should be taken to avoid overthinning of grafts with removal of a portion of the dermis (in effect creating a split-thickness graft), as this will result in graft contracture and poor aesthetic outcomes.
- The graft may be pie crusted in a few small areas by making small slits with a no. 11 knife.
 - This allows egress of fluid during the initial few days when graft adherence to the wound bed is critical. This is not critical in all cases.
- The skin graft is then inset on the wound.
 - It is tacked in a few corners with 50 chromic sutures to anchor the graft (**TECH FIG 1C**).
 - Remainder of the skin graft can be sutured with a running technique. We often use 6-0 fast-absorbing gut sutures; however, nylon sutures may also be used.
 - A bolster dressing is created with Xeroform gauze or cotton balls soaked in mineral oil to fashion a tie over bolster (**TECH FIG 1D**).

TECH FIG 1 • **A.** Cheek defect after resection with negative margins. **B.** Full-thickness skin graft marked in the infraclavicular area. **C.** Full-thickness graft has been sutured in place and Frost sutures placed to support the lower eyelid. **D.** Bolster dressing sutured in place.

■ Cheek Reconstruction With Split-Thickness Skin Graft

- Split-thickness skin grafts are useful in patients in whom a full-thickness skin graft is not available or there are contraindications for full-thickness graft harvest (eg, massive burns, inadequate donor sites, medical contraindications).
- The face and neck are prepped and draped as above. The wound bed is

prepared.

- A template of the wound is made. This is used to mark the donor site.
- Split-thickness skin grafts can be harvested from any available donor site in the body.
 - Commonly they are harvested from the thighs due to easy accessibility.
 - Split-thickness skin grafts harvested from the scalp provide a better color match.
- The donor site is injected with 0.25% bupivacaine with epinephrine for pain control and hemostasis.
- The skin graft is harvested with a dermatome at a thickness of 0.012 to 0.014 inches.
- The donor site is then covered with an epinephrine-soaked gauze pad for hemostasis.
- Split-thickness skin grafts in the face are used as sheet grafts and are not meshed. Meshed grafts on the face are cosmetically unacceptable.
 - The graft is pie crusted by making small slits with a knife. This allows egress of fluid during the initial few days when graft adherence to the wound bed is critical.
- The skin graft is then inset on the wound.
 - It is tacked in a few corners with 50 chromic sutures to anchor the graft.
 - Remainder of the skin graft can be sutured with a running suture. We often use 6-0 fast absorbing gut sutures; however, nylon sutures may also be used.
 - A bolster dressing is created with Xeroform gauze or cotton balls soaked in mineral oil to fashion a tie over bolster.
- The donor site is dressed with alginate dressing and covered with a transparent membrane dressing (Opsite).

PEARLS AND PITFALLS

Graft thickness

- Full-thickness skin grafts are preferred for facial reconstruction. They have a better color, contour, and thickness match compared to split-thickness skin grafts.
- If split-thickness grafts are used, they should not be meshed if at

	all possible as this results in a cosmetically unacceptable appearance.
Wound bed	■ The wound bed should be well vascularized. It should be debrided to remove any fibrin or nonviable tissue that will impede graft take. ■ Hemostasis should be assured because blood under the skin graft will prevent graft adherence.
Donor site	■ Skin graft donor sites from the face and neck will have the best color match. Donor sites caudal to the clavicles have poor match. ■ A template of the defect should be created. This helps to accurately plan the skin graft harvest.
Appearance	■ Skin grafts may have a patchlike appearance. This is due to the difference in color, texture, and thickness between the donor and recipient sites (FIG 3). This becomes more obvious with sun exposure as the untanned skin grafted area becomes more visible compared to the tanned native skin. ■ Patch appearance can be minimized by selecting donor sites with a color match as close as possible to the defect (FIG 4). ■ Minimal thinning of the graft (and preservation of a thin layer of subcutaneous fat) improves the long-term appearance of the graft (FIG 5).
Postoperative care	■ Any fluid collections under the skin graft should be promptly evacuated with a needle or knife blade. ■ Infections can result in graft loss and should be treated early.
Revisions	■ Procedures like dermabrasion, laser, and dermal fat grafts can improve the final aesthetic result.

POSTOPERATIVE CARE

- The skin graft and bolster are kept dry and protected from trauma.
- The bolster is removed 5 to 8 days postoperatively.
 - If there is any accumulation of fluid under the skin graft, it is evacuated with a needle or small scalpel nick.
 - A thin layer of petrolatum jelly (Vaseline) is applied twice a day for approximately 3 weeks.
- Full-thickness skin grafts: The donor site can be washed in 24 hours.
- Split-thickness skin grafts: If the alginate dressing gets soaked, it can be changed in 24 to 48 hours. Otherwise, it is changed at the time of bolster removal.

OUTCOMES

- Dermabrasion can improve the appearance of skin grafts.³
 - This is done several months postoperatively, once the skin graft has completely healed. This helps smooth areas of contour irregularities.

FIG 3 • A. Split-thickness skin graft was used to treat a large cheek defect of an obese man with multiple medical comorbidities. **B.** 1 year postoperatively. **C.** Note shrinkage of graft with time and new biopsy site with dressing.

- Patients with large skin grafts or those at high risk for hypertrophic scar formation can be treated with facial pressure garments.⁴ Silicone sheeting can also be helpful.
 - There is some evidence, however, that pressure garments may cause disturbance of facial growth in children.⁵
- Laser therapy has been shown to help improve the appearance of facial scars.⁶
 - Pulse dye lasers can be used to improve the appearance of hypertrophic and erythematous skin grafts.
- Contour depressions that are unsightly can be improved with dermal fat grafts.⁷
 - This is done at least 6 months postoperatively or even longer if graft scar maturation has not occurred.
 - These grafts can be harvested from any part of the body, commonly around a pre-existing scar or the lower abdomen.

- The dermal fat grafts are contoured to the deformity and placed under the skin graft.

COMPLICATIONS

- Complete or partial skin graft loss can occur due to a blood or fluid collection under the graft or movement of the graft preventing graft adherence.
- Hemostasis at the wound bed should be assured prior to placement of skin graft.
- The graft should be bolstered securely to prevent graft movement.
- Infections can occur at the graft or donor site.
- Graft site infections can result in sloughing of the skin graft. Patients at risk are diabetics, immunocompromised, and smokers.
- Infections should be treated early with antibiotics.
- Secondary contracture of the graft can result in contour abnormalities and distortion of adjacent structures.
- Grafts close to the lower eyelid can result in cicatricial ectropion.

FIG 4 • A,B. This cheek defect was allowed to fill in by

granulation tissue over a 3-week period, and a full-thickness skin graft was harvested from the cervical area. **C,D.** Excellent contour and acceptable skin color match are seen postoperatively.

FIG 5 • A,B. Large defect in the upper cheek and lower eyelid area. A full-thickness skin graft was harvested from the upper chest area and thinned minimally after allowing the area to granulate and fill in for 2.5 weeks. **C,D.** Excellent contour and lack of graft shrinkage are seen postoperatively.

Section IX: Ear

29 Antia-Buch Flaps for Ear Reconstruction

CHAPTER

Amir M. Ghaznavi and Brian R. Gastman

DEFINITION

- Antia-Buch flaps are best used for traumatic or postsurgical helical defects of the upper third and middle third of the ear that measure between 25% and 50% of length of the helix.¹

ANATOMY

- The ear is made up of delicate skin and soft tissues covering a cartilaginous framework and underlying muscles.
 - The cartilaginous portion of the ear includes the conchal bowl, antihelix, and helix.
 - The surrounding muscles of the ear can be divided into intrinsic muscles (muscles that originate and insert on the ear) and extrinsic muscles (muscles that originate in other regions of the skull and insert onto the ear).
- The intrinsic muscles include the helicis major, helicis minor, tragus, antitragus, transverse, and oblique muscles.
- The extrinsic muscles include the anterior, superior, and posterior auricular muscles.
- The arterial supply of the ear is derived from the posterior auricular artery and perforators arising from the superficial temporal artery.
- Venous drainage is provided by the posterior auricular veins that drain into the external jugular system as well as the superficial temporal and retromandibular veins.
- Lymphatic drainage of the ear is to the parotid, infraclavicular, mastoid, and

infraauricular cervical nodes.

- Sensory innervation of the ear is provided by:

1. Great auricular nerve (C2–C3)

- Auriculotemporal nerve (V3)
- Lesser occipital nerve
- Auricular branch of the vagus nerve (Arnold nerve)

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history and physical exam of the head and neck should be performed to document the exact location of the defect within the ear (superior third, middle third, and lower third portions) and involvement of cartilage if present.
- The patient should also be examined for evidence of nodal metastases and secondary lesions in the head and neck region. Attention should be paid to the lymph node basins in the parotid and cervical areas.
- Comorbidities that can increase the risk of postoperative wound healing and bleeding complications should be evaluated and optimized if possible.

IMAGING

- No imaging is required for Antia-Buch flaps; however, imaging of the head and neck region may be necessary to evaluate tumor metastasis.

NONOPERATIVE MANAGEMENT

- Isolated skin defects of the helical rim with intact underlying cartilage and perichondrium can heal by secondary intention or full-thickness skin grafting.
- Full-thickness skin grafts can result in excellent outcomes in patients with preserved cartilaginous support. However, healing by secondary intention or skin grafting of more complex lesions that include full-thickness excision of the underlying cartilage may result in contour abnormalities and require more complex reconstructions.

SURGICAL MANAGEMENT

Preoperative Planning

- The contours of the ear are marked preferably before skin prep to avoid washing off.
- Patients who have large defects of the ear should be counseled that they may require contralateral reduction by wedge resection and/or setback of the

unaffected ear at a later time to obtain symmetry.

Positioning

- The patient is placed in a supine position with the entire ear exposed including the hairline.
- The bed is turned 180 degrees to allow unimpeded approach to the head and neck area.
- The contralateral ear may be exposed if planning on contralateral procedure and to evaluate symmetry.

Approach

- Several surgical approaches have been described for Antia-Buch flaps including those for “classic” helix-only defects that are less than 25% of the total length of the helix, as well as modifications for longer defects and defects that include loss of the helix, scapha, and antihelix.
- Prophylactic antibiotics are administered by most surgeons particularly if the cartilage or perichondrium has been removed.
- Coverage with fluoroquinolones provides excellent cartilage penetration and provides coverage of common organisms that can cause infections of the ear (eg, *Pseudomonas aeruginosa*).
- Prolonged antibiotic treatment is usually not necessary unless the wound is contaminated or the patient is otherwise at risk for postoperative infections.

TECHNIQUES

■ “Classic” Helix-Only Defect¹

- The lesion and the proposed area of resection are identified and marked on the ear (**TECH FIG 1A**).
- The resection is performed with an incision in the helical sulcus to remove the lesion and separate the helical cartilage from the scapha (**TECH FIG 1B**).
- An incision is made in the helical sulcus (either inferiorly, superiorly, or both) extending through the anterior skin and cartilage taking care to avoid injury to the postauricular skin.

- The posterior skin is undermined superficial to the perichondrium to the level of the auricular cephalic sulcus, resulting in formation of a chondrocutaneous composite flap based on the posterior skin (**TECH FIG 1C**).
- If the defect is small (less than 10%), the inferior segment can be advanced, and the redundant Burrow triangle can be excised if necessary.
- For intermediate defects (10%–25%), both the superior and inferior portions need to be advanced for a tension-free closure (**TECH FIG 1D**).

TECH FIG 1 • **A.** Helix defect marked. **B.** Helix freed from scapha. **C.** Formation of chondrocutaneous composite flaps superior and inferior. **D.** Composite flaps advanced and closed.

■ **Modification for Defects of More Than 25% of the Helix^{1,2}**

- Defects that are more than 25% of the total length of the helix may require a modification of the classic technique of closing the defect without tension.
- The superior and inferior incisions are performed as described above to elevate the chondrocutaneous composite flaps.
- Additional mobilization of the superior segment is obtained by performing a V-Y advancement flap of the root of the helix, thereby extending the reach of the superior flap (**TECH FIG 2**).
- If additional mobilization is necessary to avoid cupping of the ear or to obtain a tension-free closure, then the advancement of the superior flap can be increased with a wedge resection of the scaphal cartilage.

- Alternatively, the superior part of the scapha can be trimmed by a few millimeters to decrease the distance that the superior flap must advance.
- However, this modification will result in shortening the height of the ear.

TECH FIG 2 • A. Making a V cut into the root of the helix. **B.** Advancement of superior segments.

■ Modification for Defects Including the Helix and Scapha³

- In some cases, resection of tumors or traumatic lesions results in loss of the helix and a portion of the scapha.
- A modification of the Antia-Buch flap can be performed by excising a crescent-shape portion of the anterior chondrocutaneous tissues on either side of the defect (**TECH FIG 3A**).
- The superior and inferior segments are then advanced using the classic approach (with or without the helical root V-Y advancement flap) to close the resulting defect (**TECH FIG 3B,C**).

TECH FIG 3 • **A.** Helical-scapal defect. **B.** Helical-scapal defect with excision of the chondrocutaneous anterior tissue. **C.** Advancement of segments.

■ **Modification (C) for Helix, Scapha, and Antihelix^{4,5}**

- Resections of the ear that include the helix, scapha, and antihelix can also be closed with modification of the classic Antia-Buch flaps.
- In these cases, wedge excisions of anterior cartilage and skin of the superior and inferior poles of the concha are performed (**TECH FIG 4A**).
- A paring incision in the concha is performed to allow tension-free advancement of the superior and inferior segments (**TECH FIG 4B**).
- The superior and inferior segments are then advanced for wound closure (**TECH FIG 4C**).

TECH FIG 4 • A. Helical-scapal-antihelix defect. **B.** Paring incision in the concha and wedge resections. **C.** Advancement of segments.

PEARLS AND PITFALLS

Hemostasis	■ Meticulous hemostasis must be obtained.
Anesthetic	■ Avoid any epinephrine on anterior aspect of pinna to avoid possibility of skin necrosis.
Surgical technique	■ Care must be taken to avoid injury to the postauricular skin flap as it is the blood supply to the chondrocutaneous flaps. ■ The dissection should be performed superficial to the perichondrium.

POSTOPERATIVE CARE

- A noncompressive dressing can be applied for comfort.
- Topical antibiotic ointment can also be applied at the discretion of the surgeon once the dressing is removed.
- No postprocedure prophylaxis is required in most cases.
- Sutures are typically removed in 7 to 10 days.

- The patient should be advised to avoid pressure on the operated ear and should refrain from sleeping on the affected side.
- Patients who wear glasses should be advised to avoid wearing glasses or remove the stem from the affected side until healing has occurred.
- Patients should also avoid applying ice to the area postoperatively.

OUTCOMES

- Ramsey et al. reported 47 patients with chondrocutaneous helical rim advancement flaps of Antia and Buch. Indications were helical rim defects of 25% to 50%.⁶
- No necrosis was reported.
- Two patients had hematomas.
- Superior cosmetic results
- Noel et al. reviewed 15 retrospective patients after modified chondrocutaneous helical rim advancement flaps.⁷
- 2.5 cm mean defect size
- Upper flap changed to transposition flap rather than advancement flap thus eliminating resection of scapha
- No skin necrosis or hematoma

COMPLICATIONS

- Skin necrosis is a rare complication but may occur in smokers or patients who have untreated hematomas.
- It is generally managed conservatively if the area is clean but may require debridement and grafting or other reconstructive procedures for extensive skin/cartilage loss.
- Ear hematoma is more common and can be problematic if it is not managed expeditiously.
- Hematoma may cause cartilage growth/deposition (so-called cauliflower deformity) and may be very difficult to manage in a delayed setting.
- Large hematomas may cause skin and cartilage necrosis and infections. Hematomas should be drained either with a needle or more commonly by reopening the incision. Drains are rarely necessary.
- Infections are rare. Most respond quickly to oral antibiotics; however, more severe cases may require intravenous antibiotics and/or incision and drainage as necessary.

- Long-term edema is also uncommon but can be problematic when it occurs. Although the etiology of this is not known, this complication is likely related to impaired lymphatic drainage.
- Lymphatic massage and compression dressings may be helpful in these instances.
- Cancer recurrence and other causes of swelling should also be ruled out.

30 Postauricular Flap for Ear Reconstruction

CHAPTER

Matthew M. Hanasono

DEFINITION

- Reconstruction of auricular defects arising from trauma or oncologic resection aims to restore the natural anatomic structures and landmarks of the ear and ideally should maintain balance and symmetry with the contralateral ear.
- Postauricular flaps are useful for reconstructing larger marginal defects of the upper and middle thirds of the auricle and are typically used in combination with cartilage grafts for reconstructing those defects that are too large for wedge or Antia-Buch chondrocutaneous advancement techniques.¹
- The postauricular flap is also known as the retroauricular flap or the Dieffenbach flap.
- Inferiorly based postauricular flaps can also be used for ear lobe reconstruction (see chapter on Reconstruction of the Ear Lobe).

ANATOMY

- The outer rim or helix creates the outer curvature of the ear and originates from the face at the root of the helix.
 - Concentrically, within the helix is the antihelix, which separates into two separate crura in the upper third of the ear that define the triangular fossa.
 - The scapha is the concave rim that separates the helix and antihelix.
 - The concha lies within the antihelix and is the structure that leads to the external auditory meatus.
 - The anterior border of the external auditory meatus is defined by the tragus.
 - In the lower third of the ear lies the lobule or ear lobe, which does not contain cartilage (**FIG 1A**).
- The blood supply to the auricle is through the posterior auricular artery and

superficial temporal artery.

- The posterior auricular artery runs in the sulcus between the auricular cartilage and the mastoid process of the temporal bone.
- This vessel supplies the posterior ear skin and posterior auricular muscle and sends perforating branches that pierce the auricular cartilage in the region of the triangular fossa, cymba conchae, cavum conchae, helical root, and ear lobe to supply the anterior ear skin (**FIG 1B**).^{2,3}
- The posterior auricular artery anastomoses with the superficial temporal artery through the superior auricular artery.
- Venous drainage is via the posterior auricular vein into the external jugular system and the superficial temporal and retromandibular veins.
- This rich anastomotic network of blood vessels is the basis for the postauricular flap.

FIG 1 • A. Anatomy of the external ear. **B.** Arterial anatomy of the posterior ear. (The right ear is shown.) The posterior auricular artery provides the blood supply for the postauricular flap. It anastomoses with the superficial temporal artery via the superior auricular artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical should be obtained prior to any operation by

paying close attention to significant comorbidities, including smoking history, prior surgeries including scars in the postauricular area, and medications that may predispose the patient to bleeding.

- Patients who wear glasses should also be educated in postoperative care and management of incisions.
 - They may need to remove the earpiece of the glasses on the reconstructed side until adequate healing has occurred, and then replace the earpiece.
- Defects resulting from oncologic resection should consider documentation for clear margins or Mohs excision prior to definitive reconstruction.

IMAGING

- Patients who have undergone resection for aggressive cutaneous malignancies may require imaging studies or staging and to rule out metastatic disease.

SURGICAL MANAGEMENT

- Postauricular flaps used in ear reconstruction can be based in the superior, middle, or inferior postauricular and mastoid region.²
- They are indicated for marginal reconstruction, in combination with cartilage grafts to support and give definition to the helix, in a staged manner as originally proposed by Dieffenbach (**FIG 2**).

Preoperative Planning

- The extent of the defect should be evaluated prior to reconstruction.
 - Postauricular flaps are preferred over wedge resections and closure, eg, for defects that encompass more than one-fourth to one-third of the outer circumference of the ear.
 - The defect size should be compared to the amount and reach of available postauricular skin.
- Pathology should be reviewed to confirm that clear margins have been obtained prior to proceeding with reconstruction.
 - In the setting of melanoma and squamous cell carcinoma, it is important also that the sentinel lymph nodes are negative as well.
- If the patient is taking anticoagulants, these should ideally be discontinued before surgery to minimize risks of hematoma.
 - If the anticoagulation cannot be continued, the patient should be made to understand the increased risks of bleeding and hematoma as complications.

Positioning

- Proper patient positioning is critical to prepare for the reconstruction again to allow the reconstructive surgeon the best access, exposure, and approach to the ear.
- The patient is placed into the supine position, and the bed can be turned 180 degrees to give access to both ears.
- It is helpful to prep and drape the entire head again to give full access and exposure to both ears.
- Local anesthetic with epinephrine is useful, despite anecdotal reports of potential risks for inducing ischemia to the ear.

FIG 2 • Method of reconstructing marginal ear defects with the postauricular flap, as originally described by Dieffenbach. The postauricular flap is initially elevated **(A)**, and the flap is transposed from the posterior auricle to the anterior auricle during inset **(B)**. A helical cartilage graft is strongly recommended to preserve the shape of the ear and give definition to the helix, although not included in the original description by Dieffenbach. At a second stage, the base of the flap is divided **(C)**, and the flap donor site is skin grafted **(D)**.

TECHNIQUES

■ Postauricular Flap for Marginal Auricular Defects

Stage 1

- The postauricular flap is used for reconstruction of marginal auricular defects that include the helix as part of a two-stage reconstruction (**TECH FIG 1A**).
- In the first stage, a posteriorly based flap is elevated and advanced anteriorly in a horizontal configuration (**TECH FIG 1B**).
 - The flap should include the subcutaneous fat but not the periosteum.
 - Although an extended retroauricular advancement flap that includes hair-bearing scalp skin has been described by Butler,⁴ in most cases, the base of the flap is in the mastoid region and the postauricular artery is not divided, if possible.
- Although the original description of the technique by Dieffenbach specified a skin flap only, a cartilage graft provides better definition of the helix and prevents collapse of the auricle as the flap heals and contracts.
 - The naturally curved cartilage from the contralateral conchal bowl serves as an excellent source of graft material.
 - Either a postauricular approach (**TECH FIG 1C**) or anterior incision made just inside the antihelical fold can be used to harvest the cartilage.

- The distal postauricular flap is used to resurface the anterior skin of the auricle (**TECH FIG 1D,E**).
 - Mattress sutures are used at the margin of the helix, to help prevent notching by providing skin eversion.
 - The auricle will be pinned back by the attachment of the flap to the mastoid region.

Stage 2

- Four to 6 weeks later, after secondary revascularization, the posterior aspect of the flap is divided.
- The ear can then be elevated, and the flap is advanced and inset into posterior surface of the auricle to complete the reconstruction.
- The mastoid donor site, which has periosteum at its base, is reconstructed with a full-thickness skin graft that is bolstered with a tie-over dressing for 5 days (**TECH FIG 2A**).
- The completed reconstruction is shown in **TECH FIG 2B**.
- A second example of a lower third auricular defect involving part of the lobule that was reconstructed with a more inferiorly based postauricular flap is shown in **TECH FIG 3**.

TECH FIG 1 • A. A helical rim defect of the central one-third of the ear. The lower incision, which has been sutured, is from a sentinel lymph node biopsy. **B.** A postauricular flap is designed, extending into the postauricular sulcus, but the postauricular artery is not divided. **C.** A contralateral conchal cartilage graft is harvested to provide support and definition to the helical rim. The graft may be obtained through an anterior or posterior (shown here) approach. **D.** The conchal cartilage graft has been secured in place with either permanent or long-acting absorbable sutures. The postauricular flap has been elevated. The plane of dissection is above the perichondrium of the ear cartilage and the periosteum of the mastoid process

bone. **E.** Completed flap inset. The edges of the flap at the margin of the ear are everted to help prevent notching at the helix.

TECH FIG 2 • A. At the second stage, 4 to 6 weeks later, the base of the flap is divided and the proximal flap is advanced onto the posterior auricle and sulcus. A full-thickness skin graft is then placed over the mastoid periosteum and secured with a bolster dressing. **B.** Postoperative results following postauricular flap and conchal cartilage graft reconstruction of a middle one-third auricular helical defect.

TECH FIG 3 • A. Lower one-third of the auricle marginal surgical defect. The auricular cartilage has been spared. **B.** Completed postauricular flap elevation, including the postauricular skin and subcutaneous fat with the flap, while preserving the perichondrium and periosteum of the donor site. **C.** Completed postauricular flap inset. **D.** Postoperative result following postauricular flap reconstruction and second-stage flap division and skin grafting of the donor site for a lower one-third auricular defect.

PEARLS AND PITFALLS

Preoperative care	■ The use of local anesthetic with epinephrine is not contraindicated in auricular reconstruction.
Technique	■ The defect should be assessed accurately to determine whether a postauricular flap reconstruction is feasible without creating a greater deformity and distortion of the ear. ■ Cartilage grafts are necessary to preserve the shape of the ear. An early result without cartilage may seem satisfactory, but without structural support, the flap will contract with time and the shape of the ear will be distorted.
Hemostasis	■ Hemostasis is critical as a hematoma can severely compromise the viability of the cartilage, distort the underlying structure, and adversely impact the final cosmetic result.
Postoperative care	■ Avoid any pressure or trauma to the reconstructed ear, including wearing of glasses and sleeping on the side of the reconstructed ear.

POSTOPERATIVE CARE

- Because permanent sutures are used to reapproximate the skin, the sutures will need to be removed in approximately 7 to 10 days.

- The incision should be cleaned regular with soap and water, paying careful attention to avoid trauma or pressure to the ear.
- Pressure dressing is usually not recommended.
- Antibiotic ointment can be used following surgery at the surgeon's discretion.
- Patients should avoid sleeping on the side of the ear that has been reconstructed.
- Patients should also refrain from wearing glasses.
 - If patients do not wear contacts and have to wear glasses, it is recommended that the earpiece on the reconstructed side be removed to avoid any potential trauma to the reconstructed ear.

COMPLICATIONS

- Infection of the ear and cartilage can be a serious complication that can lead to loss of additional cartilage and necrosis of the tissue. This can then result in a much more extensive ear defect, larger than the original defect.
 - Although extended prophylactic antibiotics are not generally recommended, a fluoroquinolone is considered the antibiotic of choice in the perioperative period due to good tissue penetration of cartilage and coverage for *Pseudomonas aeruginosa*.
- Bleeding can lead to significant distortion of the ear and underlying cartilage. Meticulous hemostasis is mandatory at the time of the operation.
- Notching of the helix is a common complication following reconstruction of marginal defects.
 - This can usually be revised satisfactorily several months later after primary healing of the cartilages and resolution of tissue edema.

31 Reconstruction of the Ear Lobe

CHAPTER

Matthew M. Hanasono

DEFINITION

- Ear lobe defects can result following trauma or following resection of cutaneous malignancies.
- The simplest types of resection and reconstruction for skin cancers on the ear lobe are amputation-type resections. These can be carried out along a curved line to approximate the curvature of the lower border of the ear lobe. Most of the procedures will result in loss of volume or height (ptosis) of the lobule.
- The ear lobe is difficult to reproduce surgically because it has a characteristic protuberance that consists of fibrofatty tissue rather than cartilage.
- Many techniques have been described for ear lobe reconstruction.^{1–8}
 - Most require more than a one-stage operation.

ANATOMY

- Ear lobes (ear lobules) occur in the lower third of the ear. They consist of areolar and fibrofatty tissue and lack cartilage.
- The ear lobes are usually about 2 cm long and may or may not be attached to the cheek to a variable degree, a characteristic that is thought to be inherited.
- The ear lobe should lie roughly even at the level of the nasal ala, which is typically half the distance between the eyes and mentum.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical should be obtained prior to any operation paying close attention to significant comorbidities, including smoking history, and prior surgeries including scars in the area that may impact the design preauricular and postauricular flaps.

- Preauricular and postauricular skin laxity should be assessed to plan whether a single folded flap can be used or if double-opposing flaps will be required.
- For example, young patients and patients who have had a face-lift may not have adequate preauricular skin laxity to create a flap and still close the donor site primarily. Sentinel lymph node biopsy and neck dissection incisions may also preclude some local flaps.

IMAGING

- Patients who have undergone resection for cutaneous malignancies such as melanoma and squamous cell carcinoma may require imaging studies for staging and to rule out potential for metastatic disease.

SURGICAL MANAGEMENT

- Numerous reconstructive techniques have been described to restore the ear lobe, all based on single or double local flaps.
- Based on the availability of preauricular and postauricular tissue, a single folded flap or double-opposing flaps can be used for ear lobe reconstruction.
 - Single flaps are usually folded and may be designed as bilobed flaps.
- Use of an anteriorly based transverse folded flap is known as Gavello procedure.³
 - The advantage of this procedure is that it is usually a single-staged procedure. A cartilage graft may be added to give support and prevent contracture, and the donor site is usually skin grafted.
 - The negative is the long length of the flap and the possibility of a donor-site scar (**FIG 1A**).
- Folded preauricular or postauricular flaps usually need a thin cartilage graft to maintain ear lobe height (**FIG 1B**).
- Double-flap reconstruction with preauricular and postauricular skin flaps usually does not require grafts (**FIG 1C,D**).⁶
- The author's preferred technique is to use double-opposing preauricular and postauricular flaps for ear lobe reconstruction.

Preoperative Planning

- Pathology should be reviewed to confirm that clear margins have been obtained prior to proceeding with reconstruction. In the setting of melanoma, it is important also that the sentinel lymph nodes are negative as well.
- The extent of the defect should be evaluated prior to reconstruction. Partial

defects are more likely to be able to be managed with a single flap and less likely to need a cartilage graft to maintain ear lobe height.

- If earrings are to be worn postoperatively, a hole in the cartilage graft, if used, will likely need to be made by the surgeon.
- If the reconstructed ear lobe cannot be made to match the contralateral ear lobe in height, the contralateral ear lobe can be reduced by performing an amputation or posterior skin transverse wedge excision.
- For single-lobe reconstructions in which a cartilage graft is used, nasal septal cartilage or conchal cartilage can be used.

FIG 1 • Some methods of ear lobe reconstruction with local flaps. **A.** Transversely oriented, bilobe flap

originally described by Gavello. **B.** Inferiorly based preauricular flap that is folded longitudinally. A cartilage graft is needed to maintain ear lobe height. **C.** Double-opposing flap technique in which a postauricular flap becomes the posterior surface of the ear lobe and a preauricular flap becomes the anterior surface of the ear lobe. No cartilage graft is usually needed. The postauricular flap is divided at its base to release the ear lobe from the postauricular (mastoid) region, and the donor site is skin grafted at a second stage. **D.** Double-opposing flap technique in which a superiorly based postauricular (infra-auricular) flap becomes the posterior surface of the ear lobe and a preauricular flap becomes the anterior surface. The donor sites are closed primarily, and a second stage may not be necessary, although, in practice, a second stage is often needed to revise the anterior attachment of the reconstructed ear lobe.

Positioning

- The patient is placed into the supine position, and both ears should be prepped and draped to give full access and exposure to both ears.
- Additionally, if septal cartilage is to be used as a graft, the nose should be exposed and prepped.
- Local anesthetic with epinephrine is useful, despite anecdotal reports of potential risks for inducing ischemia to the ear. This can also be injected into the subperichondrial plane to assist with septal cartilage harvest, in addition to applying 4% cocaine-soaked pledgets against the septal mucosa.

TECHNIQUES

■ Double-Opposing Preauricular and Postauricular

Flaps

Stage 1

- Although superiorly based postauricular skin flaps, extending into the infra-auricular neck, have been described,⁷ a more reliable postauricular skin flap is an inferiorly based one used to reconstruct the posterior surface of the ear lobe (**TECH FIG 1A**).
 - The flap is elevated from the mastoid process of the temporal bone, sparing the periosteum.
- An inferiorly based preauricular skin flap is designed (**TECH FIG 1B**).
 - The width of the flap should be at least the height of the ear lobe to be reconstructed, if possible.
 - Slight overcorrection is desirable in that the flap will contract slightly and, also, this allows the scar to be hidden posteriorly.

TECH FIG 1 • **A.** Right ear lobe defect to be reconstructed with double-opposing postauricular and preauricular flaps. The postauricular flap is elevated, leaving the mastoid periosteum intact. **B.** A preauricular flap is then elevated, leaving the parotid fascia intact. The width of this flap is ideally at least as large as the height of the original ear lobe.

- The flap should include the subcutaneous fat and be elevated above the parotid fascia.
- The flaps are opposed to each other.
- A cartilage graft is not necessary to prevent contracture in double-opposing flap reconstruction and will also make the ear lobe unnaturally stiff and bulky.
- Because the postauricular flap is still connected to the mastoid skin, the ear lobe will be pinned back temporarily until second-stage surgery.

Stage 2

- At a second stage, the postauricular skin flap is divided, releasing the reconstructed ear lobe from the mastoid region (**TECH FIG 2A**).
- The postauricular donor site is skin grafted.
- The base of the anterior flap can also be refined by partial division, if needed.
- The postoperative result is shown in **TECH FIG 2B**.

TECH FIG 2 • A. The preauricular and postauricular flaps have been joined, and at a second stage, the base of the postauricular flap has been divided, releasing the proximal flap and allowing it to be inset. The donor site is reconstructed with a full-thickness skin graft. **B.** Postoperative appearance showing good

ear lobe height and cosmesis.

PEARLS AND PITFALLS

Preoperative Care

- The use of local anesthetic with epinephrine is not contraindicated in auricular reconstruction and minimizes the need for cauterization.

Technique

- The choice of flap is made based on the laxity of the preauricular and postauricular skin.
- Single longitudinally folded flaps often contract and do not give adequate height (ptosis) unless they are very wide and a cartilage graft is added to maintain the ear lobe shape.
- Double-opposing flaps have less tendency to contract, even without cartilage grafts.
- Consider shortening the contralateral ear lobe if the reconstructed ear lobe does not match/cannot be made to match.
- Loss of ear lobe height can be avoided by not longitudinally folding a single flap or by using an anterior and a posterior flap (**FIG 2**).
- Alternately, loss of length can be avoided by placing a nonanatomic cartilage graft into a single folded flap.

FIG 2 • A. A longitudinally folded preauricular flap is used for ear lobe reconstruction. **B.** Although the reconstructed ear lobe initially looks like it has good height, it will contract because no cartilage

graft was used. **C.** Postoperative appearance, showing loss of ear lobe height.

Postoperative Care

- Avoid any pressure or trauma to the reconstructed ear including wear of glasses and sleeping on the side of the reconstructed ear.

POSTOPERATIVE CARE

- Since permanent sutures are used to reapproximate the skin, the sutures will need to be removed in approximately 7 to 10 days.
- The incision should be cleaned regularly with soap and water, paying careful attention to avoid trauma or pressure to the ear.
- Pressure dressings are not recommended, because they may compromise blood flow to the flap.
- Patients should avoid sleeping on the side of the ear that has been reconstructed.

COMPLICATIONS

- If there is significant tension on the closure, there is a risk for dehiscence.
 - Again, the patient should avoid any trauma or displacement of the ear during the early recovery period to avoid any undue tension on the closure.
- Partial or total flap loss is a risk that can be minimized by keeping skin flaps thick, to maximize vascularity, and avoiding inset under tension.
 - In some cases, tight sutures must be released, even if it means needing to do a revision or delayed wound closure.
 - Medicinal leeches may also be useful for treating flap venous congestion.

Wedge Reconstruction of Partial Auriclectomy Defects

CHAPTER

Edward I. Chang and Matthew M. Hanasono

DEFINITION

- Partial ear defects can result following trauma or more commonly following resection of cutaneous malignancies.
- Wedge resection and closure techniques are appropriate for defects up to one-third of the outer circumference of the ear occurring in the upper two-thirds of the ear.
- Reconstruction of such defects aims to restore the natural anatomic structures and landmarks of the ear and ideally should maintain balance and symmetry with the contralateral ear.^{1–3}

ANATOMY

- The ear is an important component both in the aesthetic balance of the face and in auditory function (it funnels sound into the external auditory canal and selectively amplifies sounds in the frequency range of human speech).
- The anatomic landmarks of the ear are defined by the underlying cartilaginous framework, which create the contours that should be restored as best as possible during wedge reconstruction of the ear.
- The outer rim or helix creates the outer curvature of the ear and originates from the face at the root of the helix (**FIG 1**).
- Concentrically within the helix is the antihelix, which separates into two separate crura in the upper third of the ear that define the triangular fossa.

FIG 1 • Anatomy of the auricle. Landmarks need to be precisely realigned in ear wedge resection and reconstruction.

- The scapha is the concave rim that separates the helix and antihelix.
- The concha lies within the antihelix and is the structure that leads to the external auditory meatus.
- The anterior border of the external auditory meatus is defined by the tragus. In the lower third of the ear lies the lobule or ear lobe, which does not contain cartilage.³⁻⁵
- The ideal proportions of the external ear are variable based on age and gender.
 - The length of the ear should be approximately twice the width and should project 1.5 to 2 cm from the head.⁴
 - The superior most part of the ear should be level with the position of the brow or just cephalad to the orbits, which are typically situated in the middle of the face.
 - The ear lobe should lie roughly even at the level of the nasal ala, which is

typically half the distance between the eyes and mentum.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical should be obtained prior to any operation paying close attention to significant comorbidities including smoking history, prior surgeries including scars in the area that may impact the design of the wedge resection, and medications that may predispose the patient to bleeding.
- Patients who wear glasses should also be educated in postoperative care and management of incisions.
 - They may need to remove the earpiece of the glasses on the reconstructed side until adequate healing has occurred before replacing the earpiece.
- Defects resulting from oncologic resection should consider documentation for clear margins or Mohs excision prior to definitive reconstruction.

IMAGING

- Patients who have undergone resection for cutaneous malignancies such as melanoma and squamous cell carcinoma may require imaging studies for staging and to rule out potential for metastatic disease.

SURGICAL MANAGEMENT

- Reconstruction of the ear using a wedge resection approach will result in an asymmetry compared to the contralateral ear.^{6,7}
 - The reconstructed ear will typically be smaller and may also have increased projection compared to the normal ear.
 - The anticipated result should be discussed with the patient prior to embarking on reconstruction using this technique.
- In the trauma setting, nonviable tissue should be debrided prior to definitive reconstruction.
- Topical sulfamylon can be helpful in preventing subsequent chondritis, given the effective bioavailability with cartilage penetration.
- After adequate healing and, in the case of cancer, a satisfactory surveillance period during which no recurrences are detected, wedge resection of the contralateral ear for symmetry can be offered to the patient.

Preoperative Planning

- The extent of the defect should be evaluated prior to reconstruction.
 - A wedge resection technique is appropriate for defects that encompass less

than one-third of the outer circumference of the ear.

- Larger defects will create significant projection and cupping of the ear.
- Pathology should be reviewed to confirm that clear margins have been obtained prior to proceeding with reconstruction. In the setting of melanoma and squamous cell carcinoma, it is important also that the sentinel lymph nodes are negative as well.
- Local anesthetic with epinephrine is useful, despite anecdotal reports of potential risks for inducing ischemia to the ear.

Positioning

- Proper patient positioning is critical in preparation for the reconstruction again to allow the reconstructive surgeon the best access, exposure, and approach to the ear.
- The patient is placed into the supine position, and the bed can be turned 180 degrees to give access to both ears.
- It is helpful to prep and drape the entire head again to give full access and exposure to both ears.

TECHNIQUES

■ Wedge Resection of Helix

- The length of the curvature of the missing helix is measured, and the edges of the defect are approximated using forceps to assess whether a wedge resection approach will create an unacceptable deformity, asymmetry, or poor aesthetic result.
- The edges of the helix and antihelix should be marked to ensure precise alignment of these structures.
- Local anesthetic is then injected and several minutes are allowed to achieve the desired hemostatic effect.
- The wedge excision is marked that extends into the scapha and antihelix and potentially into the concha depending on the size of the defect.
 - A full-thickness wedge is resected from the remaining ear.^{8,9}
- The cut edges of the ear cartilages are repaired first, using monofilament suture on tapered needles.

- Clinical examples of upper third and middle third wedge excision and reconstructions are shown in **TECH FIG 1**.

TECH FIG 1 • Wedge resection and reconstruction to repair partial auriclectomy defect in the superior (**A–D**) and middle (**E–H**) one-third of the ear following removal of skin cancer.

■ Variations

- A wedge-type excision and closure will typically result in a small redundancy of cartilage near the apex of the wedge, causing cupping of the reconstructed auricle.
 - This can be managed by a keyhole-type excision of cartilage (**TECH FIG 2**).
 - **TECH FIG 3** shows other wedge-type excisions.

TECH FIG 2 • Full-thickness wedge resection and reconstruction using “keyhole-type” cartilage excision to prevent redundancy of the cartilage at the apex of the wedge. Planned excision (**A**), removal of “keyhole” (**B**), and final result (**C**).

- The skin is then closed using permanent suture, everting the skin edges as much as possible.

- Mattress sutures are often helpful to maximize the eversion of the skin edges. The landmarks should be realigned based on the markings.
- The posterior skin is closed in an identical fashion using permanent sutures, again everting the skin edges as much as possible.

TECH FIG 3 • Variations of cartilaginous wedge resections to avoid redundancy of the cartilage at the

apex of the wedge and a cup deformity of the reconstructed auricle.

PEARLS AND PITFALLS

Preoperative care	■ The use of local anesthetic with epinephrine is not contraindicated in auricular reconstruction.
Technique	■ The defect should be assessed accurately to determine whether a wedge resection is even feasible without creating a greater deformity and distortion of the ear. ■ The structures of the ear should be realigned precisely with perfect skin eversion to avoid notching and a suboptimal aesthetic result. ■ A small keyhole or other type of subcutaneous cartilage excisions at the apex of the wedge can help avoid cupping of the ear.
Hemostasis	■ Hemostasis is critical as a hematoma can severely compromise the viability of the cartilage, distort the underlying structure, and adversely impact the final cosmetic result.
Postoperative care	■ Avoid any pressure or trauma to the reconstructed ear including wearing of glasses and sleeping on the side of the reconstructed ear.

POSTOPERATIVE CARE

- Because permanent sutures are used to reapproximate the skin, the sutures will need to be removed in approximately 7 to 10 days.
- The incision should be cleaned regular with soap and water, paying careful attention to avoid trauma or pressure to the ear.
- Pressure dressings are usually not recommended.
- Antibiotic ointment can be used following surgery at the surgeon's discretion.
- Patients should avoid sleeping on the side of the ear that has been reconstructed. Patients should also refrain from wearing glasses.
- If patients do not wear contacts and have to wear glasses, it is recommended that the earpiece on the reconstructed side be removed to avoid any potential trauma to the reconstructed ear.

COMPLICATIONS

- If there is significant tension on the closure, there is a risk for dehiscence. Again, the patient should avoid any trauma or displacement of the ear during the early recovery period to avoid any undue tension on the closure.
- Infection of the ear and cartilage can be a serious complication that can lead to loss of additional cartilage and necrosis of the tissue.
 - This can then result in a much more extensive ear defect, larger than the original defect.
 - Although extended prophylactic antibiotics are not generally recommended, a fluoroquinolone is considered the antibiotic of choice in the perioperative period due to good tissue penetration of cartilage and coverage for *Pseudomonas aeruginosa*.
- Bleeding can lead to significant distortion of the ear and underlying cartilage. Careful hemostasis is mandatory at the time of the operation.
- Notching of the helix is a common complication following reconstruction of the ear primarily using a wedge resection.
 - This can result from excess tension on the closure or potentially from poor technique in skin eversion but can usually be revised satisfactorily several months later after primary healing of the cartilages and resolution of tissue edema.

Section X: Nose

33 Nasal Reconstruction With Banner Flaps, Bilobed Flaps, and Nasolabial Flaps

CHAPTER

Michael V. Chiodo and Pierre Saadeh

DEFINITION

- Banner and bilobed flaps are local rotation and transposition flaps that provide well-matched color and textured skin for small (0.7–1.2 and 0.5–1.5 cm, respectively) nasal cutaneous defects.
- When compared with banner or single transposition flaps, bilobed or “double transposition” flaps can move tissue over a longer distance from the mobile soft tissue of the upper nose to the nasal tip.
- Although full-thickness skin grafts may aid in reconstructing small defects of the upper two-thirds of the nose, they are often too thin to mimic the native contours of the nasal tip.
- The nasolabial crease is one of the most important boundaries in facial aesthetics. It is the delineation between the cheek and the lips and the cheek and the nose.
- Because of its proximity to the nose and lips, flaps from this region have a critical role in nasal and cutaneous lip reconstruction.
- Nasolabial flaps are cheek flaps harvested from the strip of prominent cheek fat just lateral to the nasolabial crease referred to as the nasolabial fold.
- These flaps are most useful for small to medium-sized full-thickness skin defects of the nasal alae, caudal nasal sidewall, and upper cutaneous lip.
- They take advantage of the redundant nature of the skin of the nasolabial fold and its reliable underlying blood supply to achieve transfer of sizeable

flaps and ability for primary closure of donor defects with favorable scar placement along aesthetic unit borders.

- Nasolabial flaps are largely classified as transposition, advancement, or interpolated flaps. By definition, the base of an interpolated flap is not continuous with the defect of question, so the pedicle must cross over or under intervening tissue. Therefore, interpolated nasolabial flaps ultimately require division and inset of the flap's pedicle in a second-stage procedure, whereas transposition and advancement flaps can be done as single-stage operations.

ANATOMY

- The nose can be divided into nine aesthetic subunits with three paired units (alar base, alar wall, dorsal sidewall) and three central subunits (tip, columella, and dorsum) (**FIG 1A**).
- These units are separated by nasal contour lines between areas of different skin texture and thickness.
- Additionally, the nose can be broken into thirds based on skeletal support: proximal third is supported by the nasal bones, middle third by the upper lateral cartilages, and distal third by lower lateral cartilages (**FIG 1B**).
- The nose should be thought of as a trilaminar structure with external skin and muscle (nasalis) supported by a skeleton of cartilage and bone and an internal lining.
- Banner and bilobed flaps are random pattern cutaneous flaps dependent on the subdermal plexus for blood supply.
- The nasalis muscle, which is often included in these flaps, consists of transverse and alar parts that overlie the nasal sidewalls with an aponeurosis extending across the nasal dorsum.
- The anatomic basis for the nasolabial crease is controversial. There are two prevailing theories: a muscular theory and a fascial theory.
- Supporters of the muscular theory discuss a "fold muscle," which originates from the upper lip elevators and progresses through the nasolabial fold and crease on its way to the upper lip vermillion.
- Proponents of the fascial theory suggest the nasolabial crease is not created by muscular insertion, but rather developed by the fascial insertion of the end portion of the superficial musculoaponeurotic system (SMAS) into the skin at the junction between the upper and lower cutaneous lips and the cheek.
- There is an abundance of subcutaneous fat directly lateral to the nasolabial crease, referred to as the nasolabial fold. The skin of the cheek in this area is

loosely adherent to the deeper fascia, allowing for excellent mobility.^{1,2}

- The arterial supply to this region of the cheek is provided by facial and angular artery perforating vessels.
- Venous drainage parallels the arterial system.
- The blood supply of this region is robust to support both superiorly and inferiorly based flaps.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Given its prominence, the nose is the facial structure most susceptible to trauma as well as photodamage, which can lead to cutaneous malignancies, making it a common site for reconstruction.
- The size, depth, composition (skin, skeletal support, internal lining), and location of the defect or anticipated defect must be evaluated in addition to the surrounding skin quality, tone, and texture.

FIG 1 • A. Aesthetic subunits of the nose. **B.** "Thirds" of the nose.

- Defects caused by tumor extirpation are often the result of Mohs micrographic surgery; once margins are confirmed negative by frozen section (same day), reconstruction can proceed.
- Prior nasal operations, scars, and the effect of radiation therapy must also be taken into account when applicable.

SURGICAL MANAGEMENT

Preoperative Planning

- In the senior author's practice, nasal banner and bilobed flaps and nasolabial flaps are most commonly performed under local anesthesia. Patient preference should be considered regarding the method of anesthesia.
- Assess the mobility and laxity of the skin surrounding the defect. Cranial nasal skin is thinner and more mobile than the caudal skin and must be considered when planning flap choice and orientation.
- With proper flap planning of nasolabial flaps, scars will recreate the nasolabial crease.
- The alar facial sulcus is a crucial facial aesthetic boundary representing the convexity between the nose, cheek, and upper lip.
 - Preservation of this boundary is of critical importance in flap design and should be a primary focus during initial nasolabial flap planning.
 - Secondary revision of this region should be avoided as recreation of this convexity is challenging.¹

Positioning

- The patient is positioned supine on the operative table with their head turned to the contralateral side from the defect. Some reverse Trendelenburg with the neck in slight extension can be useful to decrease venous bleeding.
- The entire midface, at minimum, is prepped into the field to assess symmetry intraoperatively.

Approach

- Banner and bilobed flaps
 - The choice between banner and bilobed flaps is mainly dependent on defect size and location.
 - Smaller defects of the upper nasal sidewall and dorsum (0.5–1.0 cm diameter) are typically more amenable to banner flap closure. Donor-site scars are minimal, and medial canthus distortion is avoided. Banner flaps for nasal tip reconstruction often result in mismatched skin thickness resulting in unnatural topography. Larger banner flaps involve wider dissections and undermining, resulting in nasal distortion and significant standing cutaneous deformity at the pivot point.
 - Although bilobed flaps require a more extensive scar pattern, the geometrically precise design recruits mobile skin from the mid-dorsum and

sidewall to enable greater flap rotation. Better skin thickness match with less nasal contour distortion and standing cutaneous deformity is achieved at the pivot point. They are more useful for larger defects (1.0–1.5 cm diameter), particularly on the central or lateral nasal tip, ala, and caudal sidewall.

Defects on the upper half of the nose are typically not suited for bilobed reconstruction due to medial canthus distortion.

- Banner and bilobed flaps include skin, subcutaneous fat, and nasalis muscle elevated in the areolar tissue plane directly over the perichondrium (if flap is raised laterally over cartilage) or periosteum (if raised over the nasal bones). Including the nasalis makes both banner and bilobed flaps myocutaneous, adding reliable vascularity.
- Cutaneous nasal defects larger than 1.5 to 2 cm are best reconstructed with other modalities (forehead flap, dorsonasal flap, or nasolabial flap) as larger banner or bilobed flaps often leave scars that violate multiple aesthetic subunits and can result in nasal contour distortion.
- Nasolabial flaps
 - Depending on the size and location of the defect, decisions must be made regarding plane of flap elevation (cutaneous, subcutaneous, or fascial) and need for cartilaginous support for the nasal alae.¹
 - These flaps can be elevated as peninsular flaps in the cutaneous plane or island flaps when elevated in the subcutaneous plane.
 - We prefer elevation in the subcutaneous or fascial planes, taking advantage of the rich network of perforating vessels from the facial and angular artery in this area.

TECHNIQUES

■ Banner Flap

- The defect is outlined, with additional areas of excision determined in order to place scars along the borders of aesthetic subunits.
- Most often, the inferior border of the anticipated banner flap is marked tangential to the superior border of the defect and oriented in a horizontal fashion across the dorsum of the nose.
- The distance between *a* and *c* determines flap base width and can be

designed 1 to 2 mm smaller than the diameter of the defect (**TECH FIG 1**).

- Point *b* represents the tip of the flap, and when possible, this landmark is placed along a subunit border to help hide the donor-site scar.
- The length of raised tissue (*ab*) is longer than the defect size, making the flap a long and thin triangle, facilitating easy and primary closure of the donor site.
- After flap design is complete, dilute 0.5% lidocaine with 1:200 000 epinephrine is infiltrated in the subcutaneous plane.
- The flap is then raised in the areolar plane between the nasalis muscle and perichondrium/periosteum.
- The skin surrounding the flap and defect is undermined in the same areolar plane as the flap to facilitate tension-free closure.
- The flap donor site is closed first with 6-0 nylon, followed by flap transposition into the defect.
- The standing cutaneous deformity at the pivot point is assessed and removed, typically with a small Burrow triangle excised at point *a* to facilitate closure and prevent contour deformity.
- The flap is then trimmed to fit the defect precisely and inset with interrupted 6-0 nylon sutures.
- A thin layer of bacitracin is applied to the incisions twice daily until sutures are removed 5 to 7 days postoperatively.
- When sutures are removed, Steri-Strips can be applied for an additional week of support.

TECH FIG 1 • A. The flap is marked adjacent to the defect (*a*). The distance between *a* and *c* determines flap width or base and is made slightly smaller than

the diameter of the defect as the defect can be made smaller during closure. Point *b* represents the tip of the flap, and when possible, this landmark is placed in the alar crease to help hide the donor-site scar. The length of raised tissue (*ab*) is longer than the defect size, making the flap (*x*) a long and thin triangle (*b*), facilitating easy and primary closure of the donor site.

B. Flap *x* is then raised in the subnasalis plane and rotated into the defect and trimmed appropriately. **C.** A small Burow triangle can be excised at point *a*, the pivot point, to facilitate closure.

■ Bilobed Flap

- Although the original bilobed flap was designed to rotate tissue 180 degrees into a defect, this design created a large dog-ear at the point of rotation.
- Zitelli's modification of limiting total flap rotation to no more than 90 to 110 degrees decreases dog-ear formation and the risk of pincushioning.
- The flap consists of two lobes, *a* and *b*, which are used to cover the defect and close the donor site, respectively; *a* is the exact width of the defect, while *b* can be slightly narrower as tissue from the more proximal nose is more mobile and pliable.
 - The height of the second lobe is approximately 1.5 to 2.0 cm greater than the height of the first lobe.
- Markings and preoperative planning are paramount in technical execution and postoperative results.
- The planned defect is first marked and typically made circular in shape.
- The flap is designed with a pivot point located at a distance equal to the defect radius away from the defect margin. Pivot points farther away from the defect result in larger flaps, which can push each lobe off the nose, distorting either the eyelid or cheek.
 - When possible, a laterally based flap design is preferred due to improved vascularity and avoids scars over the nasal dorsum.
- We suggest using two concentric circles that share the same pivot point to aid in marking: the larger outer circle has a radius of three times the defect's

radius, whereas the smaller inner circle has a radius twice the length of the defect's (**TECH FIG 2A**).

- Premade bilobed flap templates of different sizes can be printed to provide reliable, easy, and fast bilobed flap design.
- A template of the defect is then made and placed just inside the circumference of the outer circle, adjacent to the defect, making lobe *a*.
- Lobe *b* is triangular in shape, adjacent to lobe *a*, and the farthest away from the defect; the base of this triangle is along the outside of the *inner circle* making it one defect's radius away from the circular defect.
- Lobe *a* can be curved slightly away from the defect, which includes a small Burrow triangle in its design, preventing dog-ear formation at the pivot point.
- After flap design is complete, dilute 0.5% lidocaine with 1:200 000 epinephrine is infiltrated in the subcutaneous plane.
- Incisions are made along the markings, and the flap is elevated in the areolar plane directly above the perichondrium or periosteum, always including the nasalis muscle to improve flap vasculature and maintain uniform thickness with the defect.
 - Undermining extends beyond the base and pivot point of the flap to improve mobility.
 - The skin around the flap and the defect is also undermined in the same areolar plane to facilitate tension-free closure.
- Inset begins with primary closure of the secondary donor site.
- Lobe *a* is then rotated 45 to 50 degrees into the defect and inset (**TECH FIG 2B–E**).
- The standing cutaneous deformity at the pivot point is excised and closed.
- Finally, the triangular lobe *b* is rotated into the primary donor site, trimmed to fit, and inset. Skin incisions are all closed with 6-0 interrupted nylon sutures.
- A thin layer of bacitracin is applied to the incisions twice daily until sutures are removed 5 to 7 days postoperatively.
 - When sutures are removed, Steri-Strips can be applied for an additional week of support.

A

B

C

D

E

TECH FIG 2 • A. Using two concentric circles that share the same pivot point aids in marking: the larger outer circle has a radius of three times the defect's radius, and the smaller circle's center is the defect's diameter away from the same shared pivot point (PP). **B.** The flap is undermined widely in the submuscular plane, beyond the base and pivot point of the flap, avoiding violation of neighboring aesthetic subunits when possible. Lobe *a* is then rotated 45 to 50 degrees into the defect, while the triangular lobe (*b*) is rotated into the primary donor site. Intraoperative

photographs show markings for a laterally based bilobed flap for an alar defect **(C)** that is raised in the subnasalis plane **(D)** and inset without tension or distortion of the nasal subunit **(D)**.

■ Superiorly Based Single-Stage Nasolabial Advancement Flap

- The defect is outlined, with additional areas of excision determined in order to place scars along the borders of aesthetic subunits.
- The flap is designed beginning at the medial portion of the lateral aspect of the wound.
 - A line is drawn running parallel to the nasolabial crease and should encompass a width equal to that of the wound.
 - The lateral aspect of the flap should stop at the level equal to the superior extent of the wound.
 - A 30-degree Burow triangle should be excised superior to the wound to prevent dog-ear formation (**TECH FIG 3A**).
- After completion of the flap design, dilute 0.5% lidocaine with 1:200 000 epinephrine is infiltrated in the subcutaneous plane.
- A no. 15 blade is used to complete the drawn incisions into the subcutaneous tissue (**TECH FIG 3B**).
- Using sharp dissection, the entire flap is elevated in a subcutaneous plane. The flap should be widely undermined in order to prevent a trapdoor deformity.
- The superiorly based Burow triangle is excised in a subcutaneous plane.
- After obtaining hemostasis, the flap inset begins by placement of buried deep dermal 5-0 PDS sutures. The first suture approximates the cheek skin to the periosteum in the nasofacial sulcus. The nasolabial crease is then reset by approximating the most superolateral aspect of the donor wound to the superior aspect of the alar crease.
- The flap is then thinned for flap concavity after final inset.
- The alar groove is recreated by placement of a buried deep dermal 5-0 PDS suture from the central portion of the flap to the center of the alar crease.
- The distal portion of the flap is then tailored to fit the contour of the defect

(**TECH FIG 3C,D**) with approximately 5 mm of overhang beyond the ala.

- The distal end of the flap is not inset into the defect; rather it is left open to self-tubularize around the inferior margin of the alar rim as it heals.
- The remaining incisions are closed in standard layered fashion. The author prefers deep dermal Monocryl sutures followed by a running nonabsorbable stitch.

TECH FIG 3 • A,B. Planned incisions for single-stage advancement nasolabial flap. **C.** Nasolabial flap after it has been undermined and brought into the defect. The distal aspect of the flap is tailored to fit the defect contour (*dashed line*) but left approximately 5 mm longer than the defect and left open to allow self-tubularization around the inferior margin of the ala as

it heals. The flap will be trimmed along the dashed line, and the triangular portion of transposed soft tissue will be discarded. **D.** The flap is partially inset by Prolene suture. The incision line along the nasolabial incision is closed as well as the lateral aspect of the portion of the flap filling the defect.

■ Two-Stage Interpolated Nasolabial Flap

- For subtotal nasal sidewall or alar defects, a template of the defect should be made using a pliable material such as foil.
 - If the entire nasal ala will be reconstructed, an exact template of the subunit should be made from the contralateral, normal side of the nose.
- The template is then reversed and placed along the nasolabial fold at a level superior to a horizontal line drawn through the ipsilateral oral commissure.
 - The medial border of the template should reside in the nasolabial crease, ensuring final scar closure will lie along the nasolabial crease (**TECH FIG 4A**).
 - An extra 1 mm of donor margin should be included to compensate for eventual flap contraction.
- Donor-site closure is facilitated by excision of a triangular dog-ear. The medial aspect of the flap should extend distally directly along the nasolabial crease ensuring donor-site scar camouflage.
- After completion of the flap design, dilute 0.5% lidocaine with 1:200 000 epinephrine is infiltrated in the subcutaneous plane.
- A no. 15 blade is used to complete the drawn incisions into subcutaneous tissue.
- Using sharp dissection, the entire flap is elevated in a fascial plane (**TECH FIG 4B,C**). The flap and, if possible, the recipient area should be widely undermined to prevent a trapdoor deformity.
- The proximal skin portion of the flap can be narrowed to allow for transposition, but care should be taken to encompass a broad subcutaneous flap base to preserve perforating blood supply.
- Subcutaneous fibrous bands can be carefully taken down as needed to afford adequate transposition.

- After hemostasis is achieved, flap inset begins (**TECH FIG 4D**). The most distal aspect of the flap is inset in a single-layer closure with fine, nonabsorbable, simple interrupted sutures.

TECH FIG 4 • A. Distal sidewall and superior alar defect with preoperative markings illustrating adjacent nasal subunits, proposed flap with triangular dog-ear excision placed along nasolabial fold, and arterial supply. Planned incisions are made **(B)**, and the flap is sharply elevated in the fascial plane and advanced into the defect **(C)**. **D.** The flap is then inset into the defect, with the distal aspect excised as tolerated to allow for primary closure of the donor site along the nasolabial fold. Three weeks after advancement, the patient returns **(E)**, and the flap is debulked and inset for better contour **(F)**. Pedicle division was not required in this case due to favorable orientation.

- Wide undermining of the donor site allows for tension-free closure within the nasolabial crease after excising the dog-ear at the most distal component of the donor site. The donor site is closed using a fine, nonabsorbable, running suture.
- After 3 weeks, the patient is brought back for pedicle division and flap debulking/inset (**TECH FIG 4E,F**).
 - First, the pedicle is sharply excised in an elliptical manner using a no. 15 blade, and the donor site is closed primarily. The author prefers this technique rather than proximal pedicle inset as it leaves the patient with a linear rather than V-shaped proximal end of the donor-site incision.
 - The flap is then conservatively trimmed, and final flap inset is completed using fine, nonabsorbable, simple interrupted sutures.

PEARLS AND PITFALLS

Incision placement

- Dog-ears do not settle. The flap should be completely flat at the time of surgery unless there is concern for flap viability.

Flap planning

- The choice between banner and bilobed flaps is dictated by size and location. Banner flaps are best suited for more cranial nasal

	defects under 1.0 cm. Bilobed flaps work well for caudal defects up to 1.5 cm. ■ Banner flaps crossing the midline of the nasal dorsum result in bilateral distortions that are symmetric and less obvious. ■ When truly unilateral, banner flaps may distort alar anatomy, possible narrowing the vestibule. ■ Both banner and bilobed flaps should be left completely on the nose because larger flaps can distort eyelid, cheek, and lip aesthetics. ■ The diameter of wound suitable for nasolabial flap coverage is usually less than 2.5 cm; however, this is ultimately determined by the extent of cheek laxity. ■ The convexity of the alar fascial sulcus is of particular importance when considering facial aesthetic boundaries. If the flap trajectory will cross over this region, a two-staged interpolated flap must be used. Advancement flaps crossing the alar fascial sulcus will blunt the convexity, and this deformity is very difficult to reconstruct.
Flap limitations	■ The nasolabial flap is most suitable for reconstruction of nasal alar and caudal nasal sidewall defects. Do not attempt to reconstruct the nasal tip with nasolabial flap. Such attempts are often complicated by tip necrosis and extensive trapdoor deformities.
Dermabrasion	■ Postoperative dermabrasion can even out small irregularities at suture lines and improve scar appearance.
Skin cancer	■ Consider delaying the reconstruction until the margins of resection are proven clear by histological analysis.

POSTOPERATIVE CARE

- Patients should rest with their head elevated for the first few days postoperatively.
- All facial skin sutures should be removed 5 days postoperatively.
- Drains should be removed 24 to 48 hours postoperatively.
- Postoperative antibiotic coverage is not routinely used

OUTCOMES

- In a series of 70 flaps, Elliott et al. reported only one partial flap loss, salvaged by a small revision.³
- Zitelli et al. found excellent color and texture match in all 20 patients treated with nasal bilobed flaps; the only complication was superficial epidermal necrosis in two patients.⁴

- Dog-ears, pincushioning, and donor-site concavity are the main contributors to suboptimal aesthetic outcomes.
- Nasolabial flaps provide excellent reconstruction options of the nasal ala and caudal nasal sidewall. The skin and subcutaneous tissue of the nasolabial fold provide a suitable color and texture match with the ability to camouflage scars in facial aesthetic boundaries. Proper patient selection, appropriate flap design, gentle tissue handling, and hemostasis minimize complication rates.^{5,6}
- For defects involving more than half of the alar subunit, a two-staged, interpolated nasolabial flap can provide results close to patient's normal. Full subunit reconstruction allows for camouflage of scars at subunit junctions.⁷
- A drawback of the nasolabial flap is that, in some instances, it requires a two-staged operation. Appropriate patient selection cannot be overstated.
- Need for revisional surgery is rare in the senior author's practice but should be discussed with the patient before the initial operation. Dog-ears should be excised at the time of initial operation unless there is concern for flap viability. If this is the case, it is appropriate to come back at a later date for dog-ear excision. Defects that violate the alar groove in certain instances will require a secondary operation for recreation of the alar crease.

COMPLICATIONS

- Flap necrosis
- Contour deformities, dog ears, pincushioning, and scarring
- Donor-site concavity
- Hematoma
- Infection

34 Nasal Reconstruction With Paramedian Forehead Flap

CHAPTER

Robert D. Wallace and Petros Konofaos

DEFINITION

- Nasal defects can be caused by trauma (including burns) and the sequela of skin cancer treatment by excision or radiation. Nasal defects can be partial or through and through involving all the three layers of the nose.
- Nasal reconstruction involves the use of autologous tissues to repair nasal defects.
 - All of the affected or missing parts must be replaced to achieve both an aesthetic (normal-looking nose) and a functional (easy breathing) reconstruction.
- The paramedian forehead flap (PMFF) is an interpolated axial flap based primarily off the supratrochlear neurovascular system and is well suited for reconstructing complex defects of the nose.
 - This flap produces an excellent tissue color and texture match for nasal reconstruction.

ANATOMY

Nose

- The nose consists of a pair of nasal bones that extend from the frontal bone and caudally fuse with the dorsal septum forming a support structure that extends along the length of the nasal dorsum (**FIG 1A**).
- The caudal aspect of the nasal bones overlaps the cephalic portion of the upper lateral cartilages for a distance of 2 to 4 mm.
- The upper lateral cartilages constitute the distal nasal sidewalls and extend toward the tip of the nose (**FIG 1B**).

- At their caudal free edge, they are overlapped by the cephalic portions of the lower lateral cartilages.
- The lower lateral cartilages provide the structural support to the soft tissues of the lower third of the nose.
- The nasal septum is composed of three structures: the perpendicular plate of the ethmoid posteriorly and cephalically, the vomer posteriorly and caudally, and the quadrangular septum anteriorly (see **FIG 1A**).
- The septum functions as a support structure for the midportion of the nose, and it also constitutes the medial component of the internal nasal valve.
- The blood supply to the dorsal nose is derived from the dorsal nasal artery and the anterior ethmoidal artery (**FIG 1C**).
- The lateral nasal artery, branch of the angular artery, supplies the nasal sidewalls and the caudal nasal dorsum and tip. The columellar branches of the superior labial artery with the distal branches of the lateral nasal artery supply the nasal tip from below.
- The blood supply to the septum comes from the anterior and posterior ethmoidal arteries, the sphenopalatine artery, and the posterior septal artery.
- The sensory innervation to the nose is derived from the ophthalmic (V1) (upper half of the nose) and the maxillary (V2) (lower half of the nose) divisions of the cranial nerve V. The motor innervation is from the facial nerve (VII).

FIG 1 • A–C. Anatomy of the nose.

- There are three nasal vaults:
 - The bony vault consists of the paired nasal bones and the ascending frontal process of the maxilla.
 - The upper cartilaginous vault is outlined by the paired upper lateral cartilages.
 - The lower cartilaginous vault is made of the lower lateral cartilages.
- The skin envelope of the upper two-thirds of the nose consists of thin, loose, and mobile skin with few sebaceous glands.
 - The skin of the lower third of the nose is thick and less mobile, with aberrant sebaceous glands.

Paramedian Forehead Flap

- The forehead provides a source of skin with an excellent color and texture match with nasal skin.
- The PMFF is an axial pattern interpolated flap that is based on the ipsilateral or contralateral supratrochlear neurovascular system to exit the orbit

approximately 1.7 to 2.2 cm lateral to the midline, in a vertical vector, passing under orbicularis oculi and above corrugator supercilii muscles (**FIG 2**).

- The artery, 1 cm above the brow, runs in the submuscular plane, under the frontalis, to a more superficial, subcutaneous position at the middle of the forehead.
- The PMFF consists of frontalis muscle, subcutaneous fat, and skin, except its distal portion, in which the majority of subcutaneous fat and the frontalis are removed.

PATIENT HISTORY AND PHYSICAL FINDINGS

- During the process of taking the patient's medical and surgical history, emphasis should be put on the following:
 - Case of the nasal injury, disease remission, or cancer clearance
 - Tobacco and alcohol use
 - Previous surgeries on the nose, midface, and forehead regions

FIG 2 • Design of paramedian forehead flap. M, medial side of the flap; L, lateral side of the defect; A, ala; S, skin excess.

- History of radiation therapy and/or chemotherapy
- General health status of the patient and more specifically the existence of conditions affecting wound healing and flap viability
- Patient's ethnicity
- Active drug use
- Physical examination
 - The skin of the midface and the forehead regions is inspected for scarring and previous incision sites.
 - The patency of the nasal airway should be evaluated for constrictions and/or bulky obstructing tissue, for lateral nasal wall collapse, or external nasal valve deficiency.
 - Moreover, the nose and the forehead area should be inspected for variations from normal anatomical topography.
 - Evaluation of the primary defect includes¹
 - Wound dimensions, shape, and location
 - Identification of nasal and/or facial subunits involved
 - Wound inspection for infection, constrictions, and other deformities
 - Understanding the defect in terms of tissues involved, as complex nasal defects often involve loss of lining, support, and skin cover
 - Identification of the location of the supratrochlear artery can be achieved through palpation and/or using a handheld Doppler.
 - Preoperative photography is essential to document the defect, allow outcome review and comparison, and educate the patient regarding the indicated surgical treatment.

IMAGING

- No specific radiographic imaging studies are required.
- Facial radiograph, computed tomography, or magnetic resonance imaging is occasionally employed in cancer-related cases with high risk of recurrence or to clarify bony and soft tissue injury of the midface region.

SURGICAL MANAGEMENT

- Immediate nasal reconstruction after skin tumor extirpation is safe in selected patients.
- Reconstruction is delayed when the histologic margins are questionable, the tumor histology is aggressive, in case of perineural or deep bony invasion, and when radiotherapy is to be given.

- Factors governing the choice of nasal reconstruction include donor-site morbidity, facial scarring, and the complications associated with borderline vascularity.
- Function and appearance were considered of secondary importance. On the other hand, modern nasal reconstruction emphasizes the restoration of a normal appearance and function, not on simply obtaining a healed wound.
- Millard envisioned facial landmarks as “units” and suggested to replace them in their entirety with tissue of similar color and texture to avoid a patchlike repair.
- Burget and Menick² analyzed the nose as a facial unit with subunits, based on the skin quality, border outline, and 3-D contour of each region (**FIG 3**).
- They also introduced the nasal subunit principle, which holds that, if the defect is greater than 50% of the subunits, it is better to discard adjacent normal tissue within the subunit and resurface the entire subunit rather than merely “patching the hole.” Thus, depending on the extent of the defect, wounds should be altered in size, configuration, and depth to reconstruct an entire unit.
- The subunit principle finds its ideal application for defects of the tip and alar regions because these subunits are convex and can lead to a trapdoor effect following flap inset and healing, thereby augmenting the effect of recreating the convex shape of the subunit.
- For defects of the nasal dorsum and sidewalls, the subunit principle is less applicable, because these relatively flat subunits blend indistinctly.
- The principles of ideal nasal reconstruction include
 - The exact replacement of missing tissues in dimension, thickness, and outline
 - The use of the contralateral subunit as a template for reconstruction
 - The establishment of a support framework with primary and delayed primary cartilage and bone grafts
 - Flap edges blended to the recipient site

FIG 3 • Aesthetic subunits of the nose.

- Marginal scars braced by cartilage grafts
- Detailed subcutaneous sculpture
- It is imperative to educate the patient and outline the necessary steps that will be required to repair the defect. Moreover, the patient's preferences and needs must be considered by the surgeon at the planning of the indicated reconstruction.

Preoperative Planning

- Preoperative planning should be guided by the principles of aesthetic regional unit reconstruction: alter the wound in size, outline, depth, or position, if helpful, to improve the final result. After defining the defect by means of location and missing layers, the reconstruction can be broken down into component parts, with each part addressed in turn.
- Successful reconstruction is composed of thin, conforming cover that matches nasal skin in color and texture; thin, vascular, and supple lining that does not stuff the airway; and a hard tissue framework to support, shape, and brace soft tissue against gravity, tension, and scar contraction.
- When designing the selected flap, it is important to avoid either distorting

adjacent structures or making the flap too small. When substantial amounts of all three layers are lacking, however, the reconstruction becomes more complex and less predictable.

- The PMFF is the mainstay of reconstruction for a wide variety of nasal defects.
 - For subtotal or total nasal defects, a three-stage full-thickness PMFF (with an extension to supply missing lining or combined with a septal mucosal flap) and septal or ear support grafts are used.
 - The two-stage PMFF is best suited to resurface small defects that do not require contour recreation, complex support grafts, or lining replacement. All stages are performed under general anesthesia.
- If missing, the nasal midlayer support framework must be replaced, to prevent nose collapse.
 - The support grafts can be placed primarily if vascularized lining remains or is restored with intranasal lining flaps.
 - Otherwise, the structural grafts are placed during the second stage of reconstruction with PMFF.
 - Sources for support graft for cartilage can be septal or ear cartilage and for bone calvarial or rib bone grafts.
 - Whereas septal cartilage is especially useful as a single or layered onlay dorsal graft, a tip graft, a sidewall brace, or a columellar strut, the ear remains the workhorse of tip and alar repair.
- If deficits of the internal lining cannot be closed primarily, there are several options for reconstituting it.
 - If left unrepaired, the area will heal by secondary intention with significant wound contracture, alar distortion, and nasal obstruction.
 - Punctate defects can be closed primarily, whereas an independent flap is required to repair larger defects.
 - Most commonly used options include the folded PMFF, the ipsilateral septal mucosal flap, and a full-thickness skin graft (in combination with PMFF).
- In cases in which ischemic tissue is identified, prior to reconstruction, the wound should be debrided after it demarcates itself.
 - A contaminated or infected wound should be debrided and controlled with antibiotics prior to reconstruction.
 - Significant edema and wound tension are given time to resolve.
- In cases in which the defect extends/includes to the lip and/or cheek units,

reconstruction of these areas must be established, prior to nasal reconstruction.

- Options include cheek advancement flap with/without a nasolabial extension to resurface the cheek and/or lip, an Abbe flap (if the full thickness of the upper lip is absent), or a free flap depending on the dimensions and/or depth of the defect.

Positioning

- The patient is placed supine on the operating room table in 20 to 30 degrees of a reverse Trendelenburg position.
 - This position has the advantage of decreasing intraoperative blood loss by eliminating venous pooling and flap congestion.
- Bland ophthalmic ointment is applied to the globe. The patient's eyes are closed and protected with Tegaderm.
- The full face and scalp, from the midvertex to the submental area, are prepared with a sterilization solution of the surgeon's choice.
 - A sterile head drape is placed, and full-body draping is completed in the usual sterile fashion.
- After induction of general endotracheal anesthesia, the operating room table is rotated to position the anesthesiologist at the patient's right hip.
 - Pressure points on upper extremities are padded, and a pillow is placed under the patient's knees.
 - Alternating pressure devices are applied to the lower legs.

TECHNIQUES

■ Markings and Templating

- Using a marking pen, the hairline, frown lines, subunits of the nose and lip, old scars, grafts, flaps, the location of planned vascular pedicles, areas of soft tissue excess or deficiency, and facial landmarks are marked during all stages (**TECH FIG 1A,B**).
- The path of the supratrochlear artery can be mapped out using a Doppler probe, but the author has not found this to be necessary.
 - The base of the pedicle is usually centered over the supratrochlear artery on the same side, which corresponds to the medial border of the eyebrow in

the majority of patients.

- The pedicle portion of the PMFF can be as narrow as 1.5 cm, which allows for an easier primary closure over the inferior portion of the flap (**TECH FIG 1C**).
- Templates, based on the contralateral normal, are especially helpful to determine the dimension, outline, and contour required to restore the defect.

TECH FIG 1 • Lateral (**A**) and anterior (**B**) view of preoperative markings of the nasal aesthetic subunits. **C.** The pedicle portion of the paramedian forehead flap can be as narrow as 1.5 cm, which allows for an easier primary closure over the inferior portion of the flap. **D.** Using the foil of a suture pack, a template of the contralateral normal side can be created with the silver side exposed. **E.** The template is flipped and oriented properly into the defect with the colored surface outward. **F.** The length of the pedicle is measured by a length of suture/gauze extending from the distal end of the positioned template to the level of the medial eyebrow.

- Using the foil of a suture pack, a template of the contralateral normal side can be created with the silver side exposed (**TECH FIG 1D**).
- Then, the template is flipped and oriented properly into the defect with its colored surface outward (see **TECH FIG 1E**).
- The foil-based templates can be preserved, resterilized, and reused during

later operations.

- The template is used to design the flap on the forehead skin.
 - The upper border of the template is positioned at the frontal hairline unless the patient has a receding hairline or frontal balding.
 - If the PMFF is used for covering the lining defect, the lining template is positioned as a distal extension of the covering flap with a few millimeters of excess skin between the cover and lining flaps to ease its folding.
 - If necessary, the lining extension can carry a few hair follicles (see **FIG 2**).
 - The length of the pedicle is measured by a length of suture/gauze extending from the distal end of the positioned template to the level of the medial eyebrow.
 - Then, by stabilizing the suture/gauze at the eyebrow, it is rotated 180 degrees in the coronal plane toward the midline to the most distal recipient site on the nose.
 - This step is vital to determine the exact position of the template on the forehead.
 - The flap is then precisely outlined on the forehead with a skin marker, following the exact shape of the template (**TECH FIG 1F**).
-

■ Stage 1: Elevation and Placement of the Flap

- After induction of general anesthesia and once the markings have been placed, local anesthetic (lidocaine 1% with epinephrine 1:100 000 concentration) is injected around the planned incision lines for hemostasis, sparing the lower part of the flap and the pedicle.
 - A prophylactic antistaphylococcal antibiotic of the surgeon's choice is administered intravenously.

Reconstruction of the Nasal Lining

- If a patient has a deficit of the internal nasal lining, this is repaired prior to inset of the PMFF.
- If the defect cannot be closed primarily, either an ipsilateral septal mucosal flap³ or a folded PMFF is commonly used.
- The ipsilateral septal mucosal flap is based on the septal branch of the superior labial artery.
 - Following injection of the septal mucosa with local anesthetic (lidocaine 1% with epinephrine 1:100 000 concentration), in the subperichondrial

plane along the entire length of the septum, two horizontal incisions extending from anterior to posterior are made with a scalpel on an extended handle.

- Both incisions should extend as far as posterior as possible (around 2 cm posterior to the bone-cartilage junction of the septum).
- A posterior vertical incision is then made between the ends of the dorsal and inferior septal incisions.
- The flap is dissected in the subperichondrial plane from above downward toward the floor of the nose and from posterior to anterior.
- Then, it is rotated laterally and inferiorly to line the vestibule and the lateral sidewall, with the mucosal surface facing toward the nasal passage, and is sutured in the defect.
- The exposed cartilage is left to heal by secondary intention or harvested for cartilage replacement (**TECH FIG 2**).

TECH FIG 2 • Repair of the nasal lining. After the ipsilateral septal mucosal flap is raised, it is rotated laterally and inferiorly to line the vestibule and the lateral sidewall.

- If a folded PMFF is selected for lining reconstruction, the distal lining extension of the PMFF is folded inward and sutured to the residual mucosal lining about the margin of the defect with 5-0 Vicryl Rapide interrupted

sutures.

- No primary cartilage support is placed within the folded flap at this stage.

Ala Cartilage Grafting

- Following lining reconstruction, the missing framework is substituted by means of cartilage grafts.
- For ala cartilage grafting, we use ear concha cartilage through an anterior incision.
 - The incision lies within the antihelix. It is barely visible and provides adequate exposure for harvesting the indicated amount of cartilage. In most cases, the entire concha is removed (**TECH FIG 3A,B**).
 - The incision is closed with interrupted 5-0 Vicryl Rapide sutures.
 - Quilting sutures approximate the anterior and posterior auricular skin (**TECH FIG 3C**).
- Based on the defect's size and geometry, the area that will best provide the appropriate contour and dimension is cut out from the harvested material.
 - The grafts are fixed with interrupted 5-0 chromic sutures to the residual normal skeleton, to each other, and to the underlying lining (**TECH FIG 3D**).

Flap Elevation and Donor-Site Closure

- The PMFF is incised through the skin, subcutaneous tissue, muscle, and fascia.
- Elevation of the flap is undertaken with blunt dissection in the subfascial plane, above periosteum, from superior to inferior fashion.
 - When the corrugator supercilii muscle is encountered, it is dissected from the underlying periosteum bluntly to allow greater mobility of the pedicle.
 - At this point, the supratrochlear artery may sometimes be visualized on the deep surface of the frontalis muscle just as it exits over or through the corrugator supercilii muscle.
- If the pedicle length is not sufficient, the incision is carried below the level of the eyebrow. This incision is made through skin and subcutaneous tissues.
 - Then, using blunt dissection, the pedicle is mobilized away from the medial bony orbit.
- Following flap elevation, hemostasis along the border of the flap is achieved with an electrocautery applied judiciously.
 - Donor-site closure is accomplished in layers after undermining, in the

subgaleal plane, of the skin borders up to 1 cm.

- As the wound edges are advanced, a dog-ear deformity of scalp tissue occurs at the superior apex of the flap donor-site defect. This is excised completely by extending an incision sufficiently superiorly in the scalp.
- The muscle and galea of the forehead are approximated as a single layer with simple 3-0 Monocryl sutures.
- The skin incision is repaired with simple sutures of 5-0 or 6-0 nylon. A drain is not employed.
- Any gap that cannot be approximated is allowed to heal secondarily, which takes approximately 6 to 8 weeks.

Defect Preparation

- Once it is clear that the previously raised PMFF has adequate rotation and vascularity, the defect is recreated by excising the residual skin (and scar) within the subunit, only if the defect encompasses more than half of a convex nasal subunit (the tip or ala).

TECH FIG 3 • Cartilage graft. **A.** Anterior approach for ear concha cartilage graft. **B.** The cartilage graft. **C.** The incision is closed with interrupted 5-0 Vicryl Rapide sutures. Quilting sutures approximate the

anterior and posterior auricular skin. **D.** The cartilage graft is fixed with interrupted 5-0 chromic sutures to the residual normal skeleton.

TECH FIG 4 • A. The paramedian forehead flap is rotated in the defect. **B.** Following cauterization along their entire length of the pedicle to control postoperative bleeding, the raw surface of the pedicle is dressed with Xeroform and antibiotic ointment.

- This does not apply for defects within the dorsal and sidewall subunits.
- If indicated, the remaining skin of the subunit is removed to the level of the perichondrium or periosteum.
- The skin around the nasal defect is undermined below the muscle layer for 1 cm, which helps with flap inset and prevents trapdoor deformity.

Handling of the Paramedian Forehead Flap Pedicle

- Thinning of the distal portion of the PMFF, through removal of the muscle and most of the subcutaneous fat, is important to be sufficiently supple and thin to conform to the nasal framework and manifest its contour.
- Further thinning of the PMFF is performed during the second and third stage of reconstruction.
- Following thinning, the flap is rotated into the defect and secured in place

with 5-0 nylon interrupted sutures for precise approximation of the skin edges.

- The raw borders of the pedicle of the flap are cauterized along their entire length to control postoperative bleeding, a common occurrence during the first 12 hours after surgery.
 - Some authors recommend the use of a full-thickness skin graft on the raw surface of the pedicle to avoid bleeding.
 - We have not found this step necessary and simply treat the raw surface of the pedicle with Xeroform and antibiotic ointment, thus avoiding the unnecessary use of a skin graft and the correlated donor-site morbidity (**TECH FIG 4B**).
-

■ Stage 2: Sculpture of the Nasal Repair

- Three to four weeks after the PMFF transfer into the nasal defect, sculpture of the nasal repair is performed (**TECH FIG 5A**).
 - The procedure is performed under general anesthesia to avoid the distortion created by local anesthesia or the chemical blanching of epinephrine.
 - Moreover, in cases where the folded PMFF is used, placement of cartilage grafts are also taken place at this stage.
- The nasal and regional units, the PMFF border scars, the ideal nostril rim and nostril aperture, and the excess between the cover and lining flaps are marked.
 - The ideal outline of the reconstructed ala is determined by remarking the correct rim position and outline, based on a template of the contralateral normal (**TECH FIG 5B**).
- An incision is made along the margin of right alar rim.
 - The forehead skin is easily elevated, with 2 to 3 mm of subcutaneous fat.
 - Flap elevation varies, depending on the extent of soft tissue excisional sculpture needed or the need to place additional delayed primary cartilage grafts.
 - The excess flap between the cover and lining must be eliminated (**TECH FIG 5C**).
- Following creation of an ideal subsurface shape, the forehead skin, of comparable thickness to the native nasal skin, is returned to the recipient site.

- The cover flap is secured with a single layer of 5-0 nylon interrupted sutures.
- Quilting sutures of 5-0 Vicryl Rapide are placed over the position of the alar crease in order to define the upper border of the ala (**TECH FIG 5D**).

TECH FIG 5 • **A.** Complete epithelialization of the raw surface of the pedicle is seen 2 weeks after the first

stage of reconstruction without the use of a skin graft.

B. The ideal outline of the reconstructed ala is determined by remarking the correct rim position and outline, based on a template of the contralateral normal. **C.** Elimination of the excess flap between the cover and lining. **D.** After the cover flap is secured with 5-0 nylon interrupted sutures, quilting sutures of 5-0 Vicryl Rapide are placed over the position of the alar crease in order to define the upper border of the ala.

■ Stage 3: Division of the Pedicle

- Three to four weeks later (6–8 weeks after flap transfer), the pedicle is divided.
- Lidocaine 1% containing epinephrine is injected into the base of the pedicle and circumferentially around the flap where it attaches to the nose, followed by the usual sterile preparation and draping.
- The pedicle is separated with a scalpel at the superior margin of the nasal defect.
 - An incision is made between the flap and adjacent nasal skin on either side of the pedicle to release the cephalic portion of the flap from the nose. This improves nasal contour through thinning and proper trimming and inset of the flap.
 - The incision is closed with 5-0 nylon interrupted stitches.
- The remnant of the pedicle is completely excised in a fusiform shape.
- The defect is closed along the line of the PMFF closure, thus returning the brow to its anatomic position.

PEARLS AND PITFALLS

Indications

- Reconstruction of complex post-traumatic and post-tumor excisional nasal deformities

Contraindications

- Patients with soft tissue loss, prior surgery/trauma, radiation therapy

at the forehead

- Patients unwilling or unable to tolerate multiple-stage operation

Planning

- Paramedian placement of the skin paddle leaves a more aesthetically pleasing scar and allows the potential of two PMF a single patient.
- The narrow pedicle design provides a greater arc of rotation with less chance of kinking of the vascular pedicle.
- In patients with vascular compromise, such as those with atherosclerotic disease, diabetes, or long-standing tobacco use, surgical delay of the PMFF is advised (**FIG 4**).

FIG 4 • A. Following raising of a paramedian forehead flap in an active smoker with a nasal defect, the flap showed signs of vascular compromise. Thus, a surgical delay of the flap was performed. **B.** The same flap 3 days later shows complete reversal of the vascular compromise.

Technique

- Aggressive thinning of the most distal part of the skin paddle down to the dermal plexus can be performed during the initial flap elevation or at an intermediate stage.
- Lining and structural support need to be addressed for complex nasal defects at the initial stage of PMMF elevation.
- Scars are re-excised during pedicle division, and meticulous approximation of flap edges is essential to restore optimal appearance.

POSTOPERATIVE CARE

- Postoperative care consists of cleaning the suture lines with soap and normal saline and application of antibiotic ointment twice daily for 3 days. Sutures are removed on the 7th to 10th postoperative day.
- The patient is advised to avoid excessive sunlight exposure to the forehead and face region for 6 months to prevent postinflammatory hyperpigmentation of the scars. Moreover, extremes of heat or cold may cause temporary color changes in the flap skin at the recipient site and are better avoided for several months.
- The Xeroform wrap around the raw surface of the pedicle is removed between the 3rd and 5th postoperative day, and then, it is treated with antibiotic ointment till complete epithelialization is achieved.
- The donor site of the PMFF, which cannot be closed primarily, is treated with Xeroform, antibiotic ointment, and eye patch till the 3rd to 5th postoperative day.

OUTCOMES

- Two patient examples are shown in **FIG 5**.
- Little et al.⁴ presented their experience with the use of PMFF in nasal reconstruction.
 - According to their results, the complication rate was 16.1%. Full-thickness defects and smoking were significantly associated with major complications.
 - On the other hand, age, vascular disease, or diabetes was not significantly associated with complications.
 - The authors suggested that for patients most at risk, a three-stage PMFF should be used for reconstruction.
- Paddack et al.,⁵ through a retrospective review study, studied the factors contributing to treatment failure with the PMFF in nasal reconstruction. Their study included 82 patients who underwent two-stage PMFF repair.
 - The overall failure rate was 6%.
 - No single comorbidity was noted to have a statistically significant effect on failure rates, although 83% of failures were observed in smokers.
- Kendler et al.⁶ assessed the aesthetic and functional outcomes and complications of PMFF in elderly patients with nonmelanoma skin cancer. There were 28 patients included with median age of 81 years (range, 75–95 years).
 - Although there were seven treatment-related complications, the authors

suggested that the PMFF procedure is a safe and low-risk procedure in patients 75 years of age or older with advanced nasal defects.

FIG 5 • A. This Caucasian male patient had a left ala defect following Mohs tumor excision. **B.** Long-term outcome (3 years) following a two-stage reconstruction with a PMFF. **C.** This Caucasian female patient had a

lower half nasal defect—including left ala, tip, and lower half of the dorsum—following Mohs tumor excision. **D.** First stage of reconstruction with a paramedian forehead flap. The donor site was healed by secondary intention. **E,F.** Long-term outcome (1 year) after a three-stage reconstruction with a PMFF.

- Rohrich et al.⁷ performed a retrospective analysis on 1334 patients who underwent nasal reconstruction. Three- or two-stage reconstruction was performed in 81% of the cases.
- The revision rate was 1.2%.
- The authors suggested the use of axial pattern flaps such as the PMFF for defects larger than 1.5 to 2 cm in diameter in more than two stages of reconstruction.

COMPLICATIONS

- The complication rate for PMFF is low. Hematomas, flap partial or total compromise, and poor aesthetic outcome are the most common complications.
- The development of small hematomas under the distal portion of the flap is the most common complication observed with PMFF. Hematomas develop at the time of initial flap transfer due to the rich vascularity of the flap, which creates a tendency for the undersurface of the portion of the flap thinned of its muscle and subcutaneous fat at the time of transfer to bleed postoperatively.
- To reduce the development of hematomas, careful hemostasis is needed over the entire raw undersurface of the thinned portion of the flap.
- Flap partial or total compromise is mainly due to venous congestion. This is avoidable in at-risk patients by taking the aforementioned precautions in design of the flap and use of surgical delay in indicated cases.
- Other options for salvaging a compromised PMFF include debridement followed by a second flap or graft.
- Poor aesthetic outcome include the appearance of the forehead scar, the ill-defined alar crease, the bulky nostril margin, the short nostril aperture, or an area of excess tissue.
- At 4 to 6 months, once wound maturation is complete, the alar crease can be defined by direct soft tissue excision; a hanging nostril margin trimmed by rim excision; the nasal aperture enlarged by local soft tissue excision, local

lining redistribution, or a composite skin graft, and the forehead donor scar can be revised by excision and readvanced, discarding any area of hypertrophy associated with secondary healing.

35 Septal Flaps for Nasal Lining

CHAPTER

Jordan D. Frey, John T. Stranix, and Pierre Saadeh

DEFINITION

- Nasal defects are classified on the anatomical basis of the affected nasal layer: external nasal cover or skin, bony or cartilaginous nasal support, or internal nasal lining.
- Replacement of nasal lining is considered the most imperative and challenging aspect in all of nasal reconstruction.¹
 - Poor nasal lining replacement will lead to internal scarring and contracture that will compromise the aesthetic and function of native and/or reconstructed nasal cover and support.
- Intranasal septal flaps are often favored for nasal lining reconstruction because they provide thin, reliably vascular tissue upon which cartilaginous support establishes nasal shape and support.^{2,3}

ANATOMY

- Intranasal lining transitions from the stratified squamous epithelium of the ala and columella to the mucoperichondrium of the septum and mucosa of the nasal vault.⁴
- Laterally, internal nasal mucosa is supplied by the facial and angular arteries.
- Septal mucoperichondrium is supplied by the paired septal branches of the superior labial arteries and paired anterior ethmoidal arteries^{5,6} (**FIG 1**).
 - The septal branches of the superior labial artery arise anteriorly through the orbicularis oris muscle lateral to the nasal spine at the base of the columella.
 - The anterior ethmoidal vessels arise posteriorly passing below the nasal bones to supply the dorsal septum.
- A variety of septal flaps can be designed based on these vascular pedicles to

replace deficient nasal lining.

PATHOGENESIS

- Nasal lining defects may arise from a variety of mechanisms including traumatic, oncologic, infectious, autoimmune, iatrogenic, and drug-induced etiologies.^{3-5,7}
- Although oncologic resections or traumatic injury can result in more localized defects, autoimmune and infectious etiologies more often produce pan-mucosal insult.⁴
- Nasal lining deficiencies may occur in isolation or in the context of nasal support or cover deficiencies, including full-thickness nasal defects.
- Septal flaps can be utilized for primary nasal lining defects or to cover secondary defects after other intranasal flaps have been used to provide lining for the primary defect.

NATURAL HISTORY

- Significant isolated nasal lining defects eventually result in scar contracture that can circumferentially destroy the midvault and nasal floor.⁴
- This is followed by cartilage and bone necrosis leading to loss of midvault support, tip rotation, and central facial collapse toward the piriform aperture.⁴
 - Bony nasal vault collapse is prevented by the strength of the nasal bones.⁴
- Ultimately, if external nasal skin becomes devascularized, full-thickness necrosis can occur.⁴
- Therefore, expeditious reconstruction of nasal lining defects, before the onset of scar contracture, guided by defect etiology, is strongly favored to provide optimal aesthetic and functional results.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Upon initial presentation, nasal lining defect etiology must be determined.
- If an etiology is not determined or residual disease is apparent, appropriate investigative biopsies, cultures, laboratory tests, or referrals should be arranged.⁴
 - It is imperative that the inciting etiology of the defect is rendered quiescent prior to any intervention, lest the ultimate reconstruction be compromised by ongoing pathology.

FIG 1 • The septal mucoperichondrium is largely supplied by the paired septal branches of the superior labial arteries anteriorly and paired anterior ethmoidal arteries posterodorsally.

- Possible symptoms of nasal obstruction should be elicited from the patient on history and examination because septal flaps may further compromise obstruction.
- A full extra- and intranasal physical examination should largely focus on defining the location, size, and extent of the nasal lining defect as well as any defects in nasal support or cover to guide the determination of the septal flap required.
- The subunit principle proposed by Burget and Menick is used to classify nasal cover defects and guide external nasal reconstruction.⁸
- The septal mucoperichondrium and its blood supply should be examined to ensure its integrity; injury along the nasal spine or posterior septum may indicate damage to the superior labial or anterior ethmoidal vessels, respectively.

IMAGING

- Traditional radiographic imaging is generally not necessary when planning for nasal lining reconstruction with septal flaps.
- Meticulous and standardized preoperative patient photography is mandated for both accurate operative planning and assessment of postoperative results.

DIFFERENTIAL DIAGNOSIS

- Trauma (facial fractures, foreign body)
- Oncologic (basal cell carcinoma, squamous cell carcinoma, melanoma, lymphoma)
- Infectious disease (syphilis, tuberculosis)
- Autoimmune disease (Wegener granulomatosis)
- Iatrogenic injury (septorhinoplasty, endotracheal tube pressure necrosis)
- Intranasal drug abuse (cocaine)

SURGICAL MANAGEMENT

- The use of septal flaps for nasal lining in any given defect is based on the size and location of the defect and the availability of septal mucoperichondrium; defect etiology and status of nasal cover and support are separate considerations.
- When needed, the septum proper may be harvested as graft for nasal support; care is taken to leave an adequate L strut to prevent dorsal nasal collapse.

Preoperative Planning

- Preoperatively, patient examination and photography help determine the full extent of the total nasal defect including the status of the nasal lining to develop a comprehensive operative plan.
- Patients are counseled preoperatively that multiple stages are typically required for complex nasal reconstruction and that the need for minor revisions postoperatively is likely, regardless of the type of reconstruction being pursued.
- Preparatory surgery includes debridement of necrotic or infected tissues and/or release of tethered scars at the time of or before definitive reconstruction.
 - These procedures may also take place at the time of flap delay, prelamination, or prefabrication per the reconstructive requirements.

Positioning

- Patients are positioned in the supine position with the neck in slight extension

to facilitate surgical access to the nose; this can be augmented with a shoulder roll.

- Slight reverse Trendelenburg can help decrease venous pressure and thereby bleeding.
- As required, the ears and/or chest is included in the surgical field to permit conchal cartilage or rib graft harvest for nasal support.

Approach

- If not performed in isolation, nasal lining reconstruction should precede reconstruction of nasal support and external coverage.
- The nasal lining defect is reincised to establish fresh defect edges and release any residual scar for accurate estimation of the amount of tissue required for reconstruction.
- Local hingeover or vestibular bipediced flaps with fixed sizes and less donor-site morbidity are performed first if multiple flaps are required with a septal flap for nasal lining reconstruction.
 - This allows for the harvest of the smallest possible septal flap that still provides adequate defect lining.

TECHNIQUES

■ Ipsilateral Mucoperichondrial Septal Flap

- An ipsilateral mucoperichondrial septal flap is raised based on one of the paired septal branches of the superior labial artery.
- This flap can be designed up to 3 cm in width by 3 cm in length and transposed laterally to provide lining for ipsilateral nasal vestibular and inferior sidewall defects.
- Superiorly, the flap can reach the medial canthus and, inferiorly, the nasal floor.
- To harvest the flap, an incision is made extending from the anterior area of the nasal spine upward toward the dorsum in a straight line (**TECH FIG 1A**).
- The incision travels posteriorly at a level of 6 to 8 mm below the nasal dorsum moving parallel to the dorsum and nasal bones after which it is taken inferiorly at a right angle toward the nasal floor.

- The incision continues anteriorly from the inferior aspect of the posterior vertical incision toward the nasal spine, leaving a cuff of tissue surrounding the pedicle.
 - 10 to 15 mm of cartilaginous L strut is preserved (**TECH FIG 1B**).
- The mucoperichondrium is carefully elevated off the septum.
- The flap is then transposed laterally and sutured to the edges of the defect without tension (**TECH FIG 1C–E**).

TECH FIG 1 • A. Creation of an ipsilateral mucoperichondrial septal flap begins by extending an incision from the anterior nasal spine upward toward the dorsum in a straight line; the incision carries posteriorly moving parallel along the dorsum and nasal bones before turning 90 degrees to extend

inferiorly to the nasal floor. The incision continues anteriorly toward the nasal spine, leaving a cuff of tissue surrounding the pedicle. This flap is supplied by a septal branch of the superior labial artery. **B.** Care must be taken to preserve 10 to 15 mm of cartilaginous L strut to avoid loss of structural integrity. **C–E.** This composite nasal defect required staged reconstruction. Left nasal lining was reconstructed with ipsilateral mucoperichondrial septal flap (*arrows*) that was elevated off the residual nasal septum (*yellow asterisks*) and inset laterally along the defect edge (*green line* in **E**). The nasal dorsum was reconstructed with a cantilever bone graft (*blue asterisks*), and the patient ultimately underwent external coverage that consisted of a paramedian forehead flap.

■ Contralateral Mucoperichondrial Septal Flap

- Contralateral mucoperichondrial septal flaps are utilized for moderately sized lateral sidewall nasal lining defects of the midvault that cannot be adequately covered by an ipsilateral septal flap.
- This flap is based dorsally off one of the paired anterior ethmoidal arteries.
- A contralateral mucosal flap is first designed with a width equal to the vertical height of the defect that must be covered; this width may span the entire dorsum if needed.
- Two vertical lines approximating the adequate width of the flap are drawn, extending vertically from the dorsum to the nasal floor.
- A ventral horizontal line is drawn connecting the vertical lines to complete flap design; no incision is made along the nasal dorsum.
- Once the contralateral mucosal flap is designed, a horizontal incision is made approximately 6 to 8 millimeters from the nasal dorsum on the ipsilateral mucoperichondrium.
- The ipsilateral mucosa is raised off the septum, and the septum is harvested

with care taken to leave an adequate L strut and to protect the contralateral mucoperichondrial flap.

- The contralateral flap is incised and passed through the slit in the ipsilateral mucosa after which it is transposed and sutured to the contralateral nasal lining defect (**TECH FIG 2**).
- The ipsilateral nasal bone or middle crura of the lower lateral cartilage may be resected or transected to facilitate superior or inferior flap transposition, respectively.
- The contralateral mucoperichondrial flap may be designed to extend onto the nasal floor; this will permit the flap to reach the lateral piriform aperture on the defect side.
- The ipsilateral septal mucoperichondrium must be preserved to prevent a significant septal fistula.

TECH FIG 2 • The contralateral mucoperichondrial septal flap is designed similarly to the ipsilateral septal flap. A slit is made along the nasal dorsum on the ipsilateral septal mucosa, which is then carefully lifted off the septum. The septum is harvested and may be used for nasal support as required. The contralateral septal flap may then be incised and transposed

through the slit in the ipsilateral septal mucosa into the defect. This flap is supplied dorsally by the anterior ethmoidal artery.

■ Septal Composite Hinge or Pivot Flap for Central Nasal Lining

- Cases requiring central nasal lining often coincide with subtotal or total defects of the nasal soft tissues, anterior septum, and nasal bones.
- In these circumstances, the total or remaining composite nasal septum can be elevated based on the bilateral superior labial arteries and “hinged” or “pivoted” anteriorly to provide both support and lining.
- The flap is created by making full-thickness incisions through the septum superiorly at a level approximately 1 centimeter below the dorsum and inferiorly along the nasal floor.
- A soft tissue cuff is left surrounding the pedicle in the region of the nasal spine and upper lip.
- The superior and inferior cuts are then connected with a posterior vertical cut (**TECH FIG 3**).
- The bilateral mucoperichondrium near the nasal spine is elevated off the septum, and a small piece of cartilage and bone is resected to facilitate flap transposition anteriorly.
- The superior edge of the transposed septum is secured to the remaining upper lateral cartilages or nasal bones.
 - In total nasal defects with loss of cartilaginous and bony support, bone grafting or other reconstruction of the nasal process of the frontal bone is required prior to securing the composite septal flap.
- Inferiorly based bilateral septal mucoperichondrial flaps can be raised either immediately or after delay to provide midvault and upper vault nasal lining.
- In total nasal defects, the septal mucoperichondrium will not reach inferiorly nor will it reach far enough laterally to completely line the middle and upper nasal vestibule; additional nasal lining reconstruction is required.

TECH FIG 3 • The septal composite hinge or pivot flap is created by making full-thickness cuts through the septum superiorly at a level approximately 1 centimeter below the dorsum and inferiorly along the nasal floor. A soft tissue cuff is left surrounding the pedicle similar to the ipsilateral septal flap. The superior and inferior cuts are then connected with a posterior vertical cut. Inferiorly based septal mucoperichondrial flaps can be raised bilaterally to provide nasal lining.

PEARLS AND PITFALLS

Patient history

- All patients should be assessed for smoking, which decreases intranasal septal flaps reliability.

Preoperative planning

- Templates of nasal lining defects are useful intraoperatively after all scarring has been released to help ensure the adequate septal flap design.

Flap technique	■ Septal flaps should be raised in the subperichondrial plane to protect blood supply, whether from the septal branches of the superior labial arteries or the anterior ethmoidal arteries.
Pedicle protection in anteriorly based septal flaps	■ In both the ipsilateral septal flap and composite septal hinge or pivot flap, an approximately 1.2-cm soft tissue cuff should be left intact in the area of the anterior nasal spine to protect the superior labial artery pedicle.
Combining ipsilateral and contralateral mucoperichondrial septal flaps	■ In cases of ipsilateral nasal lining defects extending from the nasal sill to the nasal bones, an ipsilateral septal flap can be combined with a contralateral septal flap for nasal lining reconstruction. ■ The ipsilateral flap covers the inferior vestibule while the contralateral flap covers the midvault and upper vault. ■ The pedicle of the ipsilateral septal flap may obstruct the external nasal valve and can be secondarily divided after the flap has healed.
Central nasal lining defects	■ The high arching nature of the midvaults and upper vaults often allows small central nasal lining defects to be closed primarily by mobilizing the medial septal and lateral sidewall mucosa.
Complications	■ Patients with severe scarring, multiple prior nasal surgeries, prior infections, or smoking history are predisposed to complications with septal flaps for nasal lining.

POSTOPERATIVE CARE

- Patients undergoing isolated nasal lining reconstruction with septal flaps may be discharged home on the same day.
- More complex nasal reconstructions requiring septal flaps in conjunction with more extensive local or microsurgical flap techniques require hospitalization.
- After discharge, patients should keep their heads elevated including at night for at least a few days to a week.
- Nasal stents may be placed at the conclusion of the procedure and generally remain in place for 3 to 4 weeks postoperatively.⁹
- Patients should avoid blowing their noses and can gently use a moist cotton-tip applicator to clean their noses as needed.
- Patients should be cautioned to expect drainage in the early postoperative period and variable nasal airway obstruction for up to 6 months after reconstruction is complete.

- Depending on the extent of the reconstruction, patients can usually quickly resume their normal daily activities but should be advised to avoid any activities that could result in injury to the face; extra care should be taken while asleep to ensure that inadvertent trauma to the nose does not occur.
- Smokers must refrain from smoking at least 1 month preoperatively and until reconstruction is completed.
- Patients should be reminded of the staged nature of most nasal reconstructions.

OUTCOMES

- Overall, patient satisfaction with nasal appearance after nasal reconstruction with septal mucoperichondrial flaps as part of overall nasal reconstruction is high (greater than 80%).^{1,4,6,7}
- Rates of objective and subjective nasal obstruction after septal flaps for lining coverage range from 0% to 31%.^{1,5,7}
- Isolated nasal lining defects undergoing reconstruction rarely result in functional nasal compromise.⁴
- Short-term postoperative nasal bleeding requiring nasal packing in this patient population is as high as 66%.⁵
- Rates of long-term nasal mucosal crusting and bleeding after nasal lining reconstruction with septal flaps range from 0% to 36% and from 0% to 6%, respectively.^{1,5,7}
- Infection and partial or complete flap necrosis are rare.^{1,5,7}

COMPLICATIONS

- Short-term complications include nasal bleeding, crusting, and obstruction.^{3,5}
- Nasal bleeding and crusting may persist long term.^{3,5,7}
- Persistent iatrogenic septal fistulae may develop after ipsilateral or contralateral septal flaps; when small, fistulae may cause whistling.¹
- Large septal fistulae from composite septal hinge or pivot flaps are inherent to flap design and generally well tolerated by patients.³
- Septal mucoperichondrial flaps inherently have little support, and if structural support is lacking, late scarring and contracture can cause late nasal distortion, stenosis, and obstruction.
- Overall, flap infection or necrosis is rare given the abundant vascularity of the face.^{1,5,7}
- Limited areas of flap necrosis can be managed conservatively and allowed to

heal secondarily if cartilage is unexposed.

- Cartilage exposure may necessitate debridement to avoid infection and local tissue necrosis.

36 Radial Forearm Flap for Nasal Lining Reconstruction

CHAPTER

Robert L. Walton and Brent Robinson

DEFINITION

- Since its initial description by Yang et al. in 1978,¹ the radial forearm flap has been considered to be one of the most versatile flaps for nasal defect reconstruction.
- It provides for thin, well-vascularized tissue that is easily harvested, with acceptable donor-site morbidity.
- Unique to the radial forearm free flap (RFFF) is its ability to be partitioned into separate islands for restoration of specific nasal lining elements such as the nasal vestibule, floor, and columella.²
- The free radial forearm flap is properly defined as a fasciocutaneous flap that is primarily based on the radial artery and its venae comitantes (VCs).
- One or two of the cutaneous nerve branches of the forearm (ulnar, median, or lateral cutaneous nerves of the forearm) provide for sensibility of the flap if a neurosensory configuration is required.³
- The size of the flap can encompass any section of the skin and fascia from the crease of the volar wrist to the antecubital fossa including the circumferential forearm.

ANATOMY

Vascular Anatomy

- The vascular anatomy of the radial forearm flap has been well elucidated.⁴ As noted above, circulatory flow is provided by the radial artery and its associated VCs (**FIG 1A**). The basilic and cephalic veins of the forearm are usually included in large configurations of the flap, although the VCs provide for its

primary venous drainage.⁴ Its long vascular pedicle (8–12 cm) and generally consistent anatomy make the radial forearm flap particularly advantageous for nasal reconstruction.

Radial Artery

- The radial artery originates just distal to the bicipital aponeurosis where the brachial artery divides into the radial and ulnar arteries. In the proximal forearm, the radial artery lies beneath the brachioradialis muscle and becomes more superficial as it approaches the hand. The radial artery travels between the heads of the first dorsal interosseous muscle to create the deep palmar arch providing blood to the thumb and thenar side of the index finger. As the radial artery becomes more superficial in the distal forearm, it gives off small fasciocutaneous perforators that course superficially to supply the overlying fascia and skin. These fasciocutaneous perforators constitute the primary perfusion of the radial forearm skin.⁴ Saint Cyr et al. found an average of 24.6 radial artery perforators in the forearm, with the majority located distally and over 50% of these having a radial orientation.⁴ The presence of these two main clusters found along the distal and proximal thirds of the radial artery can significantly facilitate flap planning and harvest.⁴
- Although variations in radial artery anatomy are rare, its collateral communications with the ulnar circulation in the hand should be confirmed preoperatively by an Allen test at the wrist. In the most common configuration of the deep palmar arch (Type A), it is formed by the anastomosis between the deep volar branch of the radial artery and the deep inferior branch of the ulnar artery.⁵ The superficial palmar arch (type A) is formed by anastomosis between the superficial volar branch of the radial artery and the continuation of the ulnar artery.⁵
- The RFFF has two systems of venous drainage: a deep system composed of two VCs accompanying the radial artery and a superficial system composed of the cephalic vein and a series of subcutaneous veins (17). The profunda cubitalis vein serves as the primary connection point between the two systems (**FIG 1B**).⁶ The superficial system is based off the cephalic vein and a series of meandering, subcutaneous venules that drain into it.⁷ The superficial venous drainage is generally considered to have a consistent course and a favorable caliber for subsequent anastomosis ranging from 3 to 6 mm.⁶ The cephalic vein courses around the radial border of the forearm ascending along the ventral aspect of the forearm toward the antecubital fossa, where it joins the basilic

vein. The cephalic vein drains the radial portion of the dorsum of the hand. Deep venous drainage occurs with the paired deep VCs that travel along each side of the radial artery with communicating tributaries. The VCs send off paired branches at each ramification of the radial artery, reproducing a triplicate pattern of vessels.⁷

- Although widely studied, the controversy of one vs two venous anastomoses still exists.⁸ Even though the published success rates of RFFF approach 95%, a series of complicating factors still can lead to unpredictable venous compromise postoperatively.⁸ In a retrospective cohort study of 370 radial forearm free flaps, Selber et al. conducted a comparative analysis of the deep vs the superficial drainage systems. They found that problems of inadequate outflow are more commonly encountered when the cephalic vein is used to drain the flap. When of adequate caliber (greater than 1 mm), they advocate using the VCs as the sole venous outflow for the flap.⁷
- As noted by Gottlieb et al., the VCs coalesce into a single vein at the level of the brachial artery bifurcation. The profundus cubitalis vein (vena anastomotica) connects the coalesced VCs to the cephalic vein at the level of the cubital fossa.⁹ By dissecting the cephalic vein proximal to this point of coalescence, both the deep and superficial venous systems can be drained via one large anastomosis. Advantages of this technique include improved venous drainage of very large radial forearm flaps, rendering the venous anastomosis technically easier, due to its larger size, and more available versatility in designing the venous portion of the vascular pedicle where the deep and superficial systems join in the proximal forearm allowing for single outflow vessel anastomosis.⁹ As noted, this configuration is reserved for large flaps that wrap the radial forearm distally and extend the greater length of the forearm to the wrist.

FIG 1 • Arterial **(A)**, venous **(B)**, and nerve **(C)**, anatomy of the radial forearm flap.

Nerve Supply

- The medial and lateral antebrachial cutaneous nerves of the forearm provide for cutaneous sensibility of the radial and volar forearm (**FIG 1C**). The lateral antebrachial cutaneous nerve is a continuation of the musculocutaneous nerve originating from C5 to C7 nerve roots and the lateral cord of the brachial plexus, and it innervates the greatest surface area of the flap's three overlapping nerve territories.⁹ The nerve arises between the biceps brachii and the brachialis muscles. It pierces the fascia radial to the biceps tendon in the cubital fossa, passes posterior to the cephalic vein, and divides into anterior and posterior branches. The larger anterior branch accompanies the cephalic vein into the forearm and supplies the skin of the radial half of the anterior surface as far as the thenar eminence. The smaller posterior branch supplies the skin of the radial border and posterior aspect of the forearm as far as the wrist. The medial antebrachial cutaneous nerve arises from C8 to T1 nerve roots. At the junction of the middle and distal thirds of the forearm, the nerve emerges from the brachial fascia running with the basilic vein and dividing into an anterior and ulnar branch. The anterior branch supplies the anterior medial surface of the forearm to the wrist; the ulnar branch passes anterior to the medial epicondyle and supplies the skin on the forearm on its posteromedial surface.
- An important attribute of the RFFF is its ability to provide restoration of sensibility in reconstruction as a neurosensory fasciocutaneous flap. Studies determining the long-term recovery of sensibility in flaps have shown increased sensibility and better functional results with reinnervated flaps compared to noninnervated flaps.¹⁰ The lateral antebrachial cutaneous nerve is the dominant nerve of the radial forearm flap, providing sensibility to over 62% of the potential flap area. It is most commonly employed for restoring sensibility in neurosensory configurations of the flap.¹⁰
- Of special note is the superficial branch of the radial nerve (SBRN), the branches of which are commonly encountered during elevation of the radial edge of the flap (**FIG 1C**). These branches are highly vulnerable to injury during flap elevation necessitating diligent care during this portion of the dissection. The SBRN courses under the brachioradialis and between the heads of the extensor carpi radialis longus just proximal to the radial styloid process.¹¹ When raising the flap, it is important to note the close relationship between the cephalic vein and SBRN. If harvest of the cephalic vein is undertaken by the surgeon during formation of the flap, an awareness of the precise anatomical location of the SBRN in relationship to both the radial artery and cephalic vein is essential to avoid neurologic injury.¹¹ Flap donor-

site morbidity arising from injury to the SBRN has been documented by Grinsell and Thiele (2005) to be between 9% and 18% depending on whether the VCs or cephalic vein were included in the elevation, as raising the cephalic vein doubled the risk of SBRN injury.¹²

PATIENT HISTORY AND PHYSICAL FINDINGS

- If an Allen test is positive but concern still exists on the patency of the radial artery, it is reasonable to obtain upper extremity arteriography for further evaluation.
- In a cadaver dissection of 650 cadaver arms, only 3.2% had no communication between the radial and ulnar artery, and 3% had an incomplete deep arch.¹³
- If both of these variations are present, the thumb will be dependent on the radial artery (approximately 1 in 1100).¹³ Vein graft reconstruction would be necessary in these cases.
- Other important components in the patient's history include hand dominance. It is preferable to harvest the flap from the nondominant upper extremity.
- Additionally, hair growth patterns on the forearm are important aesthetic considerations that may affect subsequent flap design and shape.
- A critical issue in the use of the radial forearm free flap is prior cannulation of the radial artery.
 - Arterial line catheterization traumatizes the intima, damaging vascular outflow to the perforating branches by subjecting the radial forearm flap to compromised perfusion and possible partial or complete loss.
 - Despite palpable radial pulses and a positive Allen test, flap perfusion may still be compromised.
 - History of prior arterial line catheterization should prompt consideration for use of a radial forearm flap from the opposite upper extremity or an alternate flap.

IMAGING

- Although the fine vascular perforators from the radial pedicle to the overlying skin islands can be identified using magnified contrast angiography preoperatively, we have not found such studies to be necessary owing to the plethora of fine perforating vessels emanating from the radial system in the distal forearm.
- The distribution of these vessels in the distal forearm has proved to be fairly

consistent in our experience with adequate physiologic flow provided in over 100 consecutive multi-island flaps without any perfusion issues.

SURGICAL MANAGEMENT

Preoperative Planning

- The first stage in reconstruction of total and subtotal nasal defects is restoration of the nasal lining and adjacent cheek and upper lip elements constituting the nasal base.¹⁴
- This is usually accomplished with the microsurgical transfer of a radial forearm flap to avoid compromising the local tissues and structures of the midface and airway.
- The nasal lining is composed of the floor, the nasal vestibules, and the membranous septal element (in which the columella is repaired or the midline septum is reconstituted).

TECHNIQUES

■ Templating and Flap Design

- The nasal site is dissected first, with excision of the remnant scar and any skin grafts to recreate the original defect (**TECH FIG 1A,B**).
- Templates of each of the missing lining and adjacent lip and cheek defects are made of foil from surgical suture packets.
 - Care is taken to provide sufficient skin island separation so as to accommodate the three-dimensional, anatomic positioning of these elements at the nasal site.
 - We have found it useful to attach each of the foil templates with strips of paper tape beforehand to replicate the radial vascular pedicle and then determine the best three-dimensional configuration of the islands that allows for their anatomic positioning without kinking the vascular pedicle (**TECH FIG 1C**).
- The flaps are then transferred to the forearm, where they are aligned to the radial vascular pedicle as separate skin islands (**TECH FIG 1D**).
 - For the vestibular lining element, we have found it helpful to orient the vascular pedicle at its cephalic edge so as to allow access to the nasal tip

and vestibule for placement of the supporting cartilage grafts and for sculpting without injuring the vascular pedicle.

- The vascular pedicle proximal to the skin islands should be at least 8 to 10 cm in length to allow it to span the distance from the nasal defect site to the facial artery and vein at the inferior border of the mandible.
- This precise distance is measured intraoperatively so that adequate pedicle length is obtained during flap harvest. Although vascular repairs can technically be performed more proximal near the nasal site, the marked size variability and unpredictability of the venous anatomy at this level necessitates accessing the facial system at a more anatomically predictable site, ie, below the mandibular margin.

TECH FIG 1 • **A.** An 11-year-old girl had subtotal nasal loss following a dog bite. **B.** Surgical preparation of the nasal site involves excision of all scar tissue to approximate the dimensions of the original wound. **C,D.** Foil templates of the missing nasal elements are joined with tape and aligned to the radial pedicle on the volar forearm. eds. *Microsurgical Reconstruction of the Head & Neck*. New York: Thieme Publishers, 2010:547-589 with permission.)

■ Flap Harvest

Confirmatory Dissection of The Radial Forearm Flap(s)

- Preoperatively, an Allen test is performed to assure adequate hand perfusion via the ulnar vascular pedicle.
- The 1 to 3 island radial forearm flaps are dissected under tourniquet control.
- The skin islands are kept attached at this stage of the dissection to facilitate elevation.
- The conjoined skin flap is dissected from its ulnar margin in a plane superficial to the level of the forearm fascia (**TECH FIG 2A**).
- The dissection terminates at the tendon of the flexor carpi radialis. Here, the dissection transitions to the subfascial plane.
- Small filamentous vascular branches emanating from the radial pedicle to the undersurface of the flap are easily identified and protected (**TECH FIG 2B**).
- On the radial side of the flap, the dissection proceeds through the subcutaneous tissue to the volar surface and the ulnar border of the brachioradialis tendon (**TECH FIG 2C**).
 - Care is taken here to identify and protect the dorsal sensory branches of the radial nerve and the musculocutaneous nerve.
- Occasionally, one or two small proximal branches of the radial sensory nerve may be found entering the radial forearm flap.
 - These are divided, and the proximal stumps are buried in the adjacent brachioradialis muscle to avoid painful neuroma formation.
- The dissection then proceeds deep to the radial vascular pedicle, where several relatively large branches emanating dorsally from the vascular pedicle will be encountered.
 - These are ligated with 6-0 PDS absorbable sutures and divided.
- At this point of the dissection, we have found it helpful to release the tourniquet and evaluate flap perfusion.
 - In the rare circumstance in which perfusion of the skin island is sluggish or

compromised, further flap elevation should be abandoned or delayed. The radial artery and venae comitantes (VCs) at this stage have not been divided, so little is lost.

Completion Dissection and Elevation of the Radial Forearm Flap(s)

- If the skin island demonstrates satisfactory perfusion, the tourniquet is reapplied and the flap elevation proceeds to completion.

TECH FIG 2 • A. The dissection commences on the ulnar border of the flap with elevation superficial to the deep fascia. At the radial edge of the flexor carpi radialis (FCR), the dissection is directed deep to include the radial artery and venae comitantes. **B.** Fine filamentous perforators emanating from the radial pedicle (*arrows*) to the overlying skin are preserved. **C.** On the radial side of the flap, the subcutaneous tissues are bluntly dissected to identify and preserve the dorsal sensory branches of the radial nerve (DSRN) and the distal sensory branches of the musculocutaneous nerve (MCN). At the ulnar margin of the brachioradialis tendon (BR), the dissection is directed deep to include the radial artery and its VCs (P). (Reprinted from Walton RL, Burget GC, Beahm EK. Microsurgical reconstruction of the nasal platform and lining. In: Nelligan PC, Wei FC, eds. *Microsurgical Reconstruction of the Head & Neck*. New York: Thieme Publishers, 2010:547-589, with permission.)

- Distal to the skin island, the radial artery and its two VCs are dissected out and ligated with fine 5-0 PDS absorbable suture and divided (**TECH FIG 3A**).
- A forearm incision is made over the course of the proximal radial vascular pedicle, and the vascular pedicle is dissected to its appropriate length with ligation and division of its multiple forearm muscular branches (**TECH FIG 3B**).
 - In certain situations, the microsurgical venous anastomoses can be simplified by dissection to the confluence of the VCs into a single vein just proximal to the profunda cubitalis branch joining the cephalic vein.
- After the flap has been isolated to the radial pedicle and the pedicle dissected to length, the tourniquet is released and the flap is allowed to reperfuse.
 - The pedicle and skin islands are examined under magnification to assess perfusion and to obtain final hemostasis (microbipolar and fine suture ligation of small branches).
- Separation of the skin islands and flap debulking are then performed.
 - The islands are dissected using loupe magnification, with care taken to preserve the fine, filamentous vascular branches emanating from the pedicle to each skin island.
 - Operative magnification is used to debulk selected areas of the flap (especially the vestibular element) (**TECH FIG 3C**). This is accomplished by incising the fibrous interstitium between the fat lobules and gently teasing and suctioning the fat away by a process dubbed “liposuction.” We have found this to be a very effective technique for performing the initial debulking of the acute flap without compromising its blood supply.

TECH FIG 3 • A. The radial artery and venae comitantes are ligated with fine sutures and divided after adequate flap perfusion has been verified. **B.**

The flap pedicle is dissected proximally with ligation and division of the multiple muscular branches. **C.** The flap can be debulked using operative magnification and selective excision of the fat globules peripheral to the pedicle.

■ Dissection and Exposure of the Facial Artery and Vein

- The facial vessels are exposed through a 2-cm incision made just below and parallel to the inferior mandibular border at the palpated notch or Doppler site of the facial artery pulse (**TECH FIG 4A,B**).
- The platysmal fibers are dissected apart longitudinally to expose the facial artery and vein.
 - The marginal branch of the facial nerve is identified and protected.
- A sub-SMAS tunnel connecting the nasal defect site with the facial vessel site is created using blunt dissection with progressive Hegar cervical dilators.
- The dilated tunnel is maintained with a 32 F chest catheter passed subcutaneously from the facial incision site riding the end of the retracting dilator for subsequent delivery of the vascular pedicle (**TECH FIG 4C**).

TECH FIG 4 • A. The facial vessels are accessed in the upper neck 1 to 2 cm below the lower border of the mandible. **B.** Dissection proceeds deep to the platysma with care taken to identify and preserve the marginal branch of the facial nerve. At this level, a large facial vein (3 to 4 mm external diameter; X) and facial artery (2 to 3 mm external diameter) (*arrow*) can

be identified. Occasionally, a large lymph node will be encountered that obscures access to the facial vein—dissection and removal of this lymph node will facilitate access to the facial vein. **C.** After the facial vessels have been dissected, a sub-SMAS tunnel is bluntly dissected for passage of the flap pedicle. This is progressively enlarged using cervical dilators. The dilated tunnel is maintained with a 32 F chest catheter that is passed in retrograde fashion behind the dilator. (Reprinted from Walton RL, Burget GC, Beahm EK. Microsurgical reconstruction of the nasal platform and lining. In: Nelligan PC, Wei FC, eds. *Microsurgical Reconstruction of the Head & Neck*. New York: Thieme Publishers, 2010:547-589, with permission.)

■ Transfer of Flap to Facial Site

- After the flap pedicle is divided, the flap is transferred to the nasal site where the vascular pedicle is gently directed through the subcutaneous tunnel in the cheek using the previously placed 32 F chest tube as a guide (**TECH FIG 5**).
- Gentle suction and a continuous drip of lactated Ringer solution for lubrication allow passage of the pedicle with avoidance of any vascular branch ligature avulsion or inadvertent twisting.
- Following delivery of the vascular pedicle through the cheek to the facial vessel site, the chest tube is then withdrawn, allowing the soft tissues to collapse around the unsullied pedicle.
- The flap is temporarily secured to the nasal site with 4-0 silk sutures.

TECH FIG 5 • A. Detached flap reader for transfer. **B.** At the facial site, the flap pedicle is delivered through the cheek via the previously placed chest tube. Using saline drip irrigation as lubricant and gentle suction, the pedicle is delivered to the anastomotic site. This technique allows for accurate placement of the pedicle with minimal risk for twisting or shearing of side branch ligatures. (Reprinted from Walton RL, Burget GC, Beahm EK. Microsurgical reconstruction of the nasal platform and lining. In: Nelligan PC, Wei FC, eds. *Microsurgical Reconstruction of the Head & Neck*. New York: Thieme Publishers, 2010:547-589, with permission.)

■ Flap Inset

- The vascular repairs are performed end to end to the facial artery and vein. Although no systemic anticoagulation is used, we routinely employ high-concentration heparin irrigation (50 000 units heparin/100-cc lactated Ringer solution) while performing the vascular anastomoses.
 - Aspirin (81 mg) is also administered intraoperatively and for 21 days postoperatively for its prostacyclin and antiplatelet effects.
- Following re-establishment of vascular inflow, the flap islands are arranged anatomically at the nasal site and inset with fine sutures (**TECH FIG 6A**).
- To avoid contraction of the nasal vestibular lining elements, we have found it useful to brace the vestibular element with small grafts of cadaver allograft

cartilage placed in the midline and along the caudal edge of the vestibule and secured with 6-0 PDS suture (**TECH FIG 6B,C**).

- The undersurface of the vestibular element, which now lies externally, is closed with a full-thickness skin graft from the inguinal region (**TECH FIG 6D,E**).
 - When placed over the supporting cartilage allografts, the take of the full-thickness skin graft is not compromised, as a result of its excellent capacity for bridging.
- When the grafted area is large, a fine suction drain, fashioned from a 22-gauge butterfly intravenous needle, is placed beneath the skin graft to facilitate graft adherence and promote serous drainage.
- A simple petroleum jelly-impregnated gauze/mupirocin dressing is applied to the grafted vestibular element.
- No internal nasal packing or stents are employed.

TECH FIG 6 • **A.** Following re-establishment of vascular inflow, the flap islands are arranged anatomically at the nasal site and inset with fine absorbable (chromic) sutures. **B.** The vestibular element is temporarily stented with cadaver cartilage allografts to prevent shrinkage in the interim between

the microsurgical lining flap and the placement of permanent skeletal support (autologous cartilage grafts) and a forehead flap for external cover. The graft (G) is seen spanning the vestibular element and lying beneath the vascular pedicle (P). **C.** These cartilage allografts (G) are placed along the longitudinal axis of the vestibular element and at the nostril margins and secured with 6-0 PDS sutures. **D,E.** Following inset of the flap islands, the exposed undersurfaces of the flaps are closed with full-thickness skin grafts. Full-thickness grafts stifle contraction and are useful for bridging the cadaver cartilage allografts stents. During the second stage of reconstruction, the skin grafts and cadaver cartilage grafts are removed. (Reprinted from Walton RL, Burget GC, Beahm EK. Microsurgical reconstruction of the nasal platform and lining. In: Nelligan PC, Wei FC, eds. *Microsurgical Reconstruction of the Head & Neck*. New York: Thieme Publishers, 2010:547-589, with permission.)

■ Closure of the Forearm Donor Site

- We routinely employ a full-thickness skin graft harvested from the inguinal region, which provides very stable coverage for the distal volar forearm donor site.
 - It is pliable, exhibits minimal contraction, and is aesthetically quite acceptable (**TECH FIG 7**).
- A template of the forearm defect is transferred to the inguinal region where it is incorporated within the confines of an ellipse, the longitudinal axis of which is aligned with the inguinal fold.
- For large defects, the graft may need to be applied as articulated segments derived from the confines of the ellipse.
- The graft is inset using 4-0 silk sutures that are used to secure a sponge stent.

Following application of the stent dressing, the forearm and hand are wrapped in a light compression bandage composed of Kerlix fluffs, Reston foam, Kling wrap, and an Ace wrap secured with staples.

TECH FIG 7 • Full-thickness skin grafts are preferred for closure of the forearm donor site. Here a grafted forearm donor site is shown one year postoperatively.

PEARLS AND PITFALLS

Timing

- For complex flap shapes, we have found that delay of the radial forearm flap is advantageous for augmenting dermal perfusion, and we do this routinely 10–14 days prior to flap transfer. The flap is incised all around and elevated to a variable degree above the forearm fascia depending on the size and shape complexity of the flap island. For nasal lining–only defects, two delays are performed 3–4 weeks apart.

Tendon protection

- Prior to making the skin incision, the brachioradialis and flexor carpi radialis tendons are identified at the volar wrist and traced proximally. These structures will form the boundaries of the “no-fly zone,” defining the traverse of the radial pedicle and its perforators to the overlying skin paddle. In most cases, we prefer to harvest the flap in the suprafascial plane, preserving the deep fascia for coverage of the flexor tendons and nerves. This results in less donor-site morbidity and allows for selective thinning of the flap as necessary for nasal lining reconstruction.

Perforators

- When harvesting multiple islands, it is important to use magnification

(loupe or operating microscope) to identify the radial perforators to each island. After the islands have been dissected, care should be exercised to protect each island from shear or twisting forces that might injure the perforating vessels.

Flap thickness

- Do not underestimate the thickness of this flap despite its apparent thinness in situ. This is especially relevant when transferring the flap to the face for use in nasal lining reconstruction or external nasal cover. Direct debulking of the flap prior to transfer can be effectively accomplished by using operative magnification to visualize the fat globules allowing for their lysis and direct suction removal with care to avoid injury to the radial pedicle perforators and the subdermal vascular plexus. In obese patients, pretransfer debulking/delay of the flap is essential for avoiding the typical “meatball” appearance that results from transfer of the full subcutaneous thickness of the flap.
- In certain reconstructions in which the flap is tubed for reconstruction of the columella, it is important not to coapt the opposing edges under tension as this may compromise of the blood flow. In these cases, it is helpful to apply a small full-thickness skin graft between the folded edges of the flap to ease the tension. These grafts do quite well, provided adequate hemostasis is achieved prior to application of the skin graft. If necessary, they can be excised at the time of flap debulking and contouring usually 6–8 weeks following transfer.

POSTOPERATIVE CARE

- The flap reaches maximal swelling at 48 hours.
 - Close observation must be maintained to assure that this swelling does not interfere with flap perfusion especially if multiple islands are used.
 - If there is any concern about flap perfusion as the swelling ensues, release of several inset sutures may be all that is necessary to relieve the tension and improve flap perfusion.
 - Once the swelling subsides, and usually within 3 to 4 days, the sutures can be replaced.
- If the flap is transferred to the face, care must be taken to avoid the use of cool mist face masks or blow-by oxygenation as these may result in excessive cooling of the flap, which induces vasospasm and subsequent thrombosis.
 - To avoid this complication, insist on the use of warm (steam) humidification for all oxygenation adjuncts and be sure to personally check this to assure that no cool mist is contacting the flap.
- The forearm donor-site bandage is kept in place for 1 week. It is preferable to

not use arm slings as these tend to produce shoulder stiffness, especially in older patients; patients are instructed to carry their bandaged arm upright, with overhead elbow stretching on postoperative day 1.

- The stent dressing is removed and graft take is assessed at 1 week. The graft is redressed with a petrolatum dressing and a light gauze wrap and ace bandage.
- At 10 days postoperatively, the sutures are removed and moisturizing creams are applied.
- The forearm is kept wrapped with an ace bandage or Coban elastic bandage applied by the patient for 6 weeks to stifle hypertrophic scarring and promote contouring of the forearm donor site.

OUTCOMES

- Use of the radial forearm flap for restoration of the nasal lining elements has proved to be a very reliable approach for management of challenging total and subtotal nasal defects.
- In more than 150 such cases, we have experienced only one total flap failure and six partial losses. The total flap failure occurred in a patient with Wegener granulomatosis with protein C deficiency who exhibited flap necrosis on the 4th postoperative day despite normal Doppler signals. Three partial flap losses were associated with prior radial artery cannulation.

COMPLICATIONS

- Complications inherent to the radial forearm flap are few as this is a very robust flap with large-caliber vessels and an infinite assortment of configurations and applications.
- As noted above, be wary of using the radial forearm flap if prior catheterization of the radial artery has been performed, even if the Allen test demonstrates patent communication between the radial and ulnar systems. When using the flap around hardware, be cognizant of the fact that hardware can very quickly occlude the pedicle especially as the flap swells.
- In these cases, judicious placement of the pedicle away from any restricting hardware or bone graft will be good insurance against middle of the night phone calls. If the pedicle is oriented toward the edge of the flap, as in nasal reconstruction, it is often helpful to delay the flap to assure adequate perfusion of the skin island.
- Previous trauma to the forearm with visible scarring on its volar surface should raise caution about the potential for vascular perfusion problems. In these

cases, surgical delay or choice of a different flap (or arm) is warranted.

- Over the years, we have encountered several instances of vascular spasm induced by flap contact with cool moist humidified air provided by face mask or head tent devices by respiratory therapy.
- The small size of these nasal lining flaps makes them especially vulnerable to ambient air temperatures.
- If postoperative patients require supplemental oxygen, it is important to deliver this as a warm moist humidified flow to avoid temperature-induced vasospasm.
- Experience has shown that flaps incorporating previous forearm tattoos are at risk for vascular compromise and partial flap necrosis.
- For these small flaps, it is recommended that tattoo areas of the volar forearm be excluded from the flap design whenever possible.
- After flap healing, the second stage of nasal reconstruction involves removal of the skin graft cover, debulking of the vestibular lining element, placement of cartilage support grafts, and application of a paramedian forehead flap for external cover.
- Care must be taken during this stage to avoid creating any holes in the vestibular lining flap that might communicate with the nasal airway to avoid infection.
- If the radial forearm lining flap has been compromised during the dissection, these injuries should be meticulously repaired. We have found it useful to cover these repair sites with small dermis grafts as an added level of protection.

Nasal Reconstruction With Skin Grafts and Composite Grafts

37

CHAPTER

Steven M. Levine and Daniel C. Baker

DEFINITION

- Nasal defects are frequently not amenable to primary closure without distortion of the underlying cartilaginous structure or obvious repositioning of the nasal tip or ala.¹
- Nasal defects are commonly treated with the local flaps or local regional flaps.
- The ideal reconstruction is skin of similar color, thickness, and texture.
- One-stage reconstruction is an attractive option to both patient and surgeon.
- Full-thickness skin grafts, for the purposes of this text, include the epidermis, dermis, and often adipose tissue.
- Composite grafts include both a component of skin as well as cartilage.

ANATOMY

- Nasal anatomy is often divided into aesthetic subunits.
 - These subunits are a useful guide but quite frequently can be ignored when reconstructing the nose with full-thickness skin grafts or composite grafts.
- Maximizing surface area for graft take is of primary concern when using full-thickness skin grafts or composite grafts.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Skin/subcutaneous defects on the nose may be treated in many cases with a full-thickness skin graft. However, if the defect includes missing cartilage or would benefit from extra-anatomical cartilage (such as an alar rim or tip), a composite graft should be considered.
- The defect must have an appropriate graft recipient bed to accept either graft.

- This means if the wound has been heavily cauterized during the resection portion of the procedure, excisional debridement and local wound care should be performed until a suitable bed is present.
- If the defect is contaminated as in the case of a dog bite or motor vehicle accident, debridement and local wound care should be performed until a clean recipient bed is present.
- Care should be taken to note the length, width, and depth of the defect.

SURGICAL MANAGEMENT

- Full-thickness skin grafting or composite grafting can be performed under local anesthesia, sedation, or general anesthesia, depending on the preference of the surgeon and the patient.

Preoperative Planning

- The primary consideration for preoperative planning is to define the extent of the defect and identify a suitable donor site.
- In general, color match is improved by selecting a donor site that is anatomically close to the nose (eg, the ear, preauricular skin).
 - These grafts have better color and texture match to the nose.
- The preauricular region is an ideal donor site and usually heals with an inconspicuous scar. Strong preference is given to this site vs the retroauricular site despite the natural inclination to use the more “hidden” skin behind the ear.
- Occasionally, the supraclavicular skin is good color and texture match for the nose.
- The surgeon should identify the components of the donor tissue required to optimize the aesthetic outcome.
 - Frequently, a thin layer of adipose tissue should be harvested with the grafts to allow for appropriate depth matching between the graft and the recipient site.
 - It is important to avoid overthinning of full-thickness skin grafts as this may result in late contracture or a cobblestone appearance of the graft that is difficult to address.
- The two most common donor sites for composite grafts used for nasal reconstruction are the anterior helical rim, which can be harvested along with a pennant of preauricular skin, and the conchal bowl, which can be harvested with either conchal skin or retroauricular skin.

Positioning

- The patient is either supine if under sedation or full anesthesia or sitting reclined or supine in an exam chair if performing the graft on an awake patient.

Approach

- The approach to the graft can be varied from surgeon to surgeon with a consistent emphasis on delicate handling of the graft both at the time of harvest and when securing it to the recipient site.

TECHNIQUES

■ Graft Repair of Nasal Defect

Site Preparation and Graft Harvest

- The donor site and recipient site are cleaned with alcohol and then prepped with Betadine.
- A small amount of eye ointment is placed on the sclera to protect the eyes if using anesthesia.
- First, the recipient site is defined. This means that any nonviable tissue is debrided and a fresh wound edge is created using a sharp knife to bevel the perimeter (**TECH FIG 1**).
 - Hemostasis should ideally be obtained using pressure and patience to avoid burning the recipient site and impeding graft take.
 - Very light cautery can be used if needed.
- After the recipient site is prepared, a foil template is made and transferred to the donor site.
- If a composite graft is planned for an alar defect with a lining deficiency that is greater than 8 mm, it will usually require a turndown flap.
- The authors prefer to use the adjacent sidewall skin as a turndown flap that is secured using 5-0 absorbable suture.
- Other surgeons prefer a septal hinge flap, but we find this flap to be flimsy and difficult to control.

TECH FIG 1 • Recipient site prepared.

- The graft is harvested entirely with a knife, and the edges are beveled.
- If the graft is a composite graft with cartilage, care is taken to not separate the cartilage from its attachments to the surrounding skin.

Graft Placement

- If alar reconstruction is being performed, a tongue in groove closure is performed with the composite graft cartilage and the recipient alar rim—in other words, extend the graft cartilage beyond the skin and use this additional cartilage to insert in both lateral recipient sites.
- 6-0 monofilament sutures are used to sew the grafts to the deep recipient bed to minimize potential space.
- The graft is secured usually using 6-0 nylon suture in the recipient bed (**TECH FIG 2**).
- Prior to finishing, a 20-gauge angiocatheter is used to irrigate beneath the flap with saline.
- If a bolster is used, it is secured to the flap with tape, not suture.
- The donor site is closed primarily, elevating tissue where needed to minimize tension on the closure.

TECH FIG 2 • Composite graft sewn in place with edges beveled and delicately approximated to surrounding tissue. Conchal skin was harvested with cartilage to add structure to avoid notching the alar rim.

PEARLS AND PITFALLS

Handle grafts with care

- Do not cauterize when harvesting the grafts. Do not inject local anesthesia through the graft, rather inject around the graft.

Graft take is a reflection of the health of the recipient bed

- Exercise patience when determining the appropriate timing for the graft. Fresh eschar is not a suitable recipient bed as in the case of a cauterized post-Mohs defect. Use local wound care principles to obtain a healthy granulation bed prior to grafting.

6-0 monofilament sutures to minimize potential

- These small monofilaments and accompanying small needles are an excellent alternative to through-and-through basting sutures.

space

Meticulous postgraft care

- See these grafts frequently over the first few days. Minor problems can be treated thereby avoiding major problems. Small collections can be rolled out from beneath the graft; Silvadene can be used in compromised regions. Often, epidermolysis heals and completely recovers.

FIG 1 • The patient in TECH FIGS 1 and 2 one year after composite graft for alar rim reconstruction.

POSTOPERATIVE CARE

- Tie-over bolsters have been abandoned in favor of either no bolster (for grafts smaller than 1 cm) or a small Xeroform bolster covered with nonstick gauze and tape.
- Cool packs are also used to reduce swelling and have reportedly been shown to improve graft survival by lowering the metabolic requirement of the grafted tissue.
- Patients are instructed to use cool compresses at home for the first 12 hours.
- Patients are seen back in the office the following morning, and any dressing over the graft is removed, and a cotton-tipped applicator is used to roll over the graft and express any collected fluid to avoid interference with graft imbibition. This is repeated daily for the first 2 or 3 days.
- Silvadene 1% is used TID on any compromised area of the graft.

OUTCOMES

- The surgeon should follow their first several grafts very closely to understand

the progression of healing so that they know what to expect and can convey to the patients the normal healing of the grafts.

- In the case of composite graft (or full-thickness grafts with significant adipose tissue), they are usually pale for the first day, then turn blue (congestion) for 2 or 3 days, but a small amount of pink hue is usually seen behind the blue and emerges dominant between days 5 and 6 (**FIGS 1 to 4**).
- Healing goes on for at least 1 year after grafting, and all revisions should ideally be considered only after this point.

FIG 2 • Full-thickness skin graft with preservation of fat for nasal tip reconstruction. **A.** Preoperative. **B.** Eleven months postoperatively.

FIG 3 • Full-thickness skin graft with preservation of fat for nasal tip reconstruction. **A.** Preoperative. **B.** Eleven months postoperatively.

COMPLICATIONS

- The most feared complication is complete graft loss. This is exceedingly rare.
 - Partial graft loss can occur and is usually the result of an inadequate graft bed or retained fluid collection beneath the graft.
- Step-offs between graft skin and native skin can occur if appropriate beveling of the recipient site and graft are not carried out.
- Infections can occur but should be minimized with appropriate aseptic technique. The authors do not use routine postoperative antibiotics.
- Blood pressure control is important to prevent recipient site bleeding and graft loss.

38 V-Y Advancement Flaps for Nasal Reconstruction

CHAPTER

Julian J. Pribaz and Simon G. Talbot

DEFINITION

- There are multiple different types of V-Y flaps. It is important to differentiate these especially with respect to their use in nasal reconstruction, as they must be applied correctly for successful outcome:
 - A *classic V-Y flap* refers to a triangle-shaped island flap designed at one edge of a defect with the tapering V part distal to the defect (**FIG 1A**).
 - It is based on a mobile subcutaneous pedicle.
 - As the triangular flap is advanced into the defect, the residual donor site is closed primarily, resulting in a Y-shaped scar.
 - It is essential that there is an adequate and mobile pad of subcutaneous fatty tissue to allow flap advancement.^{1,2}
 - The *extended V-Y flap* is a modification of the V-Y advancement flap, with the addition of an extension limb onto the advancing edge of the standard flap (**FIG 1B**).
 - The limb is located adjacent to the area requiring reconstruction and is elevated from its bed and hinged down as a transposition flap on the end of the V-Y advancement flap to close the most distal part of the defect.
 - A *double extended V-Y flap* is an even larger flap, with an extension limb on each side of the defect, so that both limbs are transposed onto the advancing edge of the V-Y flap, which itself is based on a mobile subcutaneous pedicle.³

FIG 1 • Perforator V-Y flaps based on the angular artery, showing a regular V-Y design for a more vertically oriented defect **(A)** and an extended V-Y design for a more medial and circular defect **(B)**.

- The *V-Y perforator flap* is an entirely different concept, and the only similarity with the above is that the eventual donor-site closure goes from a V to a Y configuration.
 - Unlike the regular V-Y flaps, the perforator flaps are not based on a broad mobile subcutaneous pedicle but rather on specific perforating vessels that must be mobilized for flap advancement.

ANATOMY

- The cutaneous anatomy of the nose is not uniform.
- The skin in the upper half is thinner and has a variable amount of underlying subcutaneous fat, with the most mobility over the nasal bridge just below the

glabella.

- The lower half of the nose is thicker and more sebaceous and also much more adherent with very little mobility due to lack of subcutaneous fat.
- The blood supply is rich and comes from the paired angular arteries and accompanying veins.
- The angular artery starts at the alar base as a continuation of the facial artery and runs in the trough between the nasal side wall and adjacent cheek. It anastomoses with the infraorbital, infratrochlear, and dorsal nasal vessels and across the midline with corresponding vessels on the opposite side. It gives multiple small perforators that pass both medially onto the nose and laterally onto the cheek (**FIG 2**).⁴
- There is relatively loose areolar tissue with some fat around the pedicle, which provides flap mobility.
- The type of V-Y flap that can be used successfully will depend on the location of the defect on the nose.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients present with small, yet often challenging, defects of the nose that are usually the result of tumor excision.
- In many cases, these patients have undergone Mohs surgery involving complete excision of the tumor with clear microscopic margins, making it safe to proceed with immediate reconstruction.
- The location, size, shape, and orientation of the defect are important in determining the method of reconstruction.
- The goal is to restore the nose to as near normal as possible, especially with respect to the contour restoration with no distortion to the natural landmarks of the nose.
- Any surgery will produce scars, but contour restoration is more important because scars do settle and mature with time to becoming less conspicuous.
- Ideally, the use of adjacent local tissue will ensure that the best color and texture will be restored.

FIG 2 • Vascular supply to the nose. The angular artery starts at the alar base as a continuation of the facial artery and runs in the trough between the nasal side wall and adjacent cheek. It anastomoses with the infraorbital, infratrochlear, and dorsal nasal vessels and across the midline with corresponding vessels on the opposite side.

- The use of V-Y advancement flaps brings in local “like tissue” that causes a minimum distortion.
- The type of V-Y flap that is used depends on the site of the defect.
 - The classic V-Y flap is possible only in the proximal nose across the nasal bridge, where there is more subcutaneous tissue and the flap can be advanced effectively and expeditiously in a transverse direction.
 - For defects of the distal half of the nose, a perforator type V-Y flap is used. This may be extended or doubly extended for additional reach (see **FIG 1**).
 - For vertically oriented defects, a perforator flap without extensions will

suffice.

- For round, more transversally oriented defects or defects that are more medially located, an extended type of V-Y perforator flap is needed.

SURGICAL MANAGEMENT

Preoperative Planning

- For simple V-Y flaps across the nasal bridge, no special planning is needed other than assessing the mobility of the soft tissues and designing the transverse V-Y flap.
- For defects in the distal half of the nose, the beginner should use a Doppler ultrasound to map out the angular artery and perforators, but once experienced, this is not necessary because there are consistent, multiple perforators.
- The flap is designed adjacent and lateral to the defect, with the V component extending across the nasal-cheek junction to capture the perforators.
 - The orientation of the flap has a slight downward or oblique tilt, so that eventually once transferred into the defect, the flap is entirely on the nose and does not cross the nose-cheek junction.

Positioning

- The procedure is short and usually performed under local anesthesia in a day surgery setting, with the patient in supine position.
- The procedure could be done under MAC anesthesia or rarely under general anesthesia.
- It is best to inject the local anesthetic before prepping and draping the patient to allow the anesthetic and epinephrine to take effect.
 - We have not had any problems with the use of epinephrine with the local anesthetic.

Approach

- The approaches are different according to the type of V-Y flap as described above.
- Loupe magnification may be used for the perforator-type flap dissection, especially if inexperienced.

TECHNIQUES

■ Classic V-Y Flap for Proximal Nasal Defects

- The usual defect is on the lateral side of the nasal bridge and medial canthal area.
- A transversely oriented V-Y flap is designed and infiltrating with local anesthesia.
- Once this has taken effect, simple skin incision and minimal blunt dissection is adequate to mobilize the flap and complete the repair (**TECH FIG 1**).

TECH FIG 1 • Basal cell carcinoma of the left inner canthus marked to be excised and repaired with classic V-Y flap.

■ Perforator V-Y Flap for Defects of the Distal Half of the Nasal Side Wall and Supra-alar Region

Standard Perforator V-Y Flap

- The flap is marked as described above (**TECH FIG 2A**).
- Local anesthesia with epinephrine is infiltrated along the flap margins, including the nose-cheek junction where the perforators are located.
- The skin is incised, and the flap nearest the defect is completely elevated off the underlying tissue toward the nose-cheek junction.
- The lateral V aspect of the flap is incised down to the subcutaneous tissue

only, and then blunt, spreading type of dissection is performed with fine scissors, teasing out the deeper subcutaneous fatty tissue and the perforators.

- The perforators are readily visualized, but no attempt is made to isolate the flap on a single perforator (**TECH FIG 2B,C**).
- The mobilization is continued until adequate mobilization has been achieved to allow the flap to move into the defect with minimum tension.
- The inset is performed in a single layer, with nylon attempting to evert the wound edges for a better repair and help to minimize pincushioning due to scar contracture (**TECH FIG 2D**).
 - Deeper absorbable sutures are used to repair the donor site, with the repair falling along the nasolabial fold.
- The flap appears pink, well perfused, and not congested at the end of the operation despite the use of epinephrine with the local anesthetic.
- This is usually performed as a single-stage procedure, but secondary minor scar revisions may occasionally be required.

Extended Perforator V-Y Flap

- For more medially located defects, or more transversely oriented defects, an extended type of flap design is used, and the advancing extension wings are sutured together to increase the reach.
 - The suture line of the extension flap often falls along a natural crease line at the junction between the alar subunit and the lateral domal subunit, so it becomes less conspicuous with time (**TECH FIG 3**).
 - Perforator V-Y flaps are generally not indicated for defects involving the nostril margins.
- Although the V component of the flap starts on the cheek, after transfer, it should lie completely within the nose, with Y closure being made along the nasolabial fold.
- The V-Y perforator flap should not disrupt the alar subunit. Its lower border can be just along the supra-alar crease, but not cutting across it or distorting it.

TECH FIG 2 • A. Patient following Mohs surgery with a more circular defect medially located, with perforator flap design. Perforators marked as dots along nose-cheek junction. **B.** Perforator dissection medially. **C.** Perforator dissection laterally. **D.** Flap inset.

TECH FIG 3 • **A.** Patient with defect at domal/alar groove with flap marked curving over the alar subunit. **B.** Flap inset.

PEARLS AND PITFALLS

Indications and assessment

- Have a clear understanding of the different types of V-Y flaps that may be used for nasal reconstruction and where they can be applied.

Technique

- Cannot do a conventional V-Y flap in the distal half of the nose due to lack of mobile subcutaneous tissue.
- Where there is limited tissue mobility, a perforator-type flap is required. Do not skeletonize the pedicle.
- An extended perforator V-Y flap is required for larger, transversely oriented, and more medially located defects.
- Perforator V-Y flaps can “start on the cheek” but must “end up on the nose.” It should not span the nose-cheek junction.
- Inset flap with everting suturing to minimize pincushioning.

POSTOPERATIVE CARE

- Skin-colored Steri-Strips are usually applied as the only dressing.
- The Steri-Strips may need to be replaced in a day or so if they become blood

stained.

- The sutures are removed at a week and the usual scar management protocol followed.

OUTCOMES

- The V-Y flap provides a simple and reliable way of reconstructing small yet difficult nasal defects, either of the bridge of the nose with a simple V-Y flap or distal half of the nose with a perforator V-Y flap, both providing an aesthetic reconstructive outcome (**FIG 3**).^{5,6}

COMPLICATIONS

- Scar contracture and pincushioning can be minimized with careful and everting skin edge suturing.
- Minor scar revisions can be performed if needed once the scars have had a chance to mature.

FIG 3 • Postoperative appearances of the patients in TECH FIGS 1A, 2B, and 3C,D.

CHAPTER Facial Artery Perforator Flap

Julian J. Pribaz and Simon G. Talbot

DEFINITION

- Perforator flaps are a relatively recent addition to our reconstructive techniques.
- They have evolved as a result of meticulous studies of vascular blood supply to the skin, which have demonstrated a rich network of perforator vessels arising from all major vessels, allowing for the elevation of safe and customized flaps based on these vessels.
- The facial artery is the major vessel supplying the lower half of the face. Multiple innovative flaps have been developed based on perforators arising along the course of the facial artery, including flaps in the perioral region, which is the subject of this chapter.^{1–6}

ANATOMY

- Arterial
 - The facial artery enters the face by hooking around the lower border of the mandible at the anterior edge of the masseter muscle. It follows a tortuous course through the cheek, passing upward and medially toward the oral commissure and then to the alar base, where it becomes the angular artery (**FIG 1**).
 - It passes deep to the muscles of facial expression and gives off two major named vessels—the inferior and superior labial arteries—as well as multiple perforators to all surrounding structures, including the superficial and deep muscles, skin, and mucosa.

- Hofer mapped out the perforators supplying the skin and found that these were multiple, with at least three perforators having an average diameter of 1.2 mm. His injection studies showed that a single perforator can supply a large area of facial skin, thus making it useful for perioral reconstruction.⁷

FIG 1 • Arterial supply of the lower face and mouth.

■ Venous

- The main facial vein does not run with the artery but is located more laterally in the cheek and approaches the facial artery near the angle of the mandible.
- There are multiple small venous channels in the soft tissues that provide adequate drainage to perforator flaps. However, it is important not to skeletonize the pedicle but rather leave a cuff of soft tissue to allow for venous drainage.
- This is an important distinguishing feature of facial artery perforator flaps compared with those harvested from other parts of the body in which the perforating vessels are routinely skeletonized to maximize flap reach and rotation. Because of the tortuous nature of the artery and the mobility of tissues in this region, it is still possible to rotate safely the flap up to 180 degrees.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The soft tissues making up the nasolabial fold and jowl area are lax and mobile. Fortunately (from the reconstructive point of view), these qualities increase with aging, when the need for flaps from this donor site also increases to deal with surrounding defects created after tumor extirpation. The tissue laxity facilitates primary repair of the donor site.
- In addition, this area of the skin lies directly over the course of the facial artery and its perforators, allowing for safe flap elevation and repair.
- Superiorly and inferiorly based pedicled nasolabial flaps with a skin bridge have been used successfully since ancient times. The inclusion of a skin bridge makes the flap bulky, limits its mobility, and distorts the surrounding anatomy. It also requires a secondary procedure to divide and inset the flap.
- A better understanding of the anatomy of perforators refined and developed island flaps supplied by one or more perforators devoid of skin bridge, which has made it easier to rotate the flap and perform more one-stage reconstructions.
- Perforator flaps based on the facial artery can be considered for all substantial defects of the perioral region, lips, distal nasal, and cheek (**FIG 2**).
- They have the advantage of using local “like tissue” adjacent to the defect, which results in aesthetically superior reconstructions. This includes the use of hair-bearing skin from the jowl area for mustache and beard reconstruction.
- As the facial artery is sandwiched between the superficial muscles of facial expression and the deeper buccinator and mucosa (which are all supplied by the facial artery), it is possible to raise a composite full-thickness cheek island flap if this is what is needed for reconstruction.

FIG 2 • A. Patient with nostril sill and upper lip defect after excision of basal cell carcinoma. **B.** Superiorly based island perforator nasolabial flap. **C.** After single-stage flap transfer.

- To avoid injury to the muscles of facial expression, the deep part of this flap can be harvested just inferior to the risorius muscle, where only the buccinator muscle is taken with the flap (**FIG 3**).

IMAGING

- A facial artery perforator flap is most often indicated for reconstruction after tumor excision, and imaging may be required for oncological assessment to ensure adequate resection. No special imaging is needed for operative planning, however.

SURGICAL MANAGEMENT

Preoperative Planning

- A careful diagnosis of the defect or deformity is required, and the suitability of facial artery perforator flap is assessed. This will be made based on the location, size, and depth of the defect as well as the subunits of the face, lip, cheek, and nose involved.
- Will a single facial artery perforator be adequate to complete the reconstruction?
- Is there adequate laxity in the surrounding tissues to allow closure of the donor site with minimal deformity?
- Can this be done in a single stage? If not, the patient needs to be counseled about possible revisions and secondary procedures, especially if the defect spans different subunits.
- The integrity and location of the facial artery and its perforators are assessed with a Doppler ultrasound.
- There are multiple perforators along the course of the facial artery, but it is best to choose the perforator closest to the defect to enable the flap to rotate into the defect with the least tension.
- Templates of the defect and subunits (using the contralateral side) are used to design the flap, which usually abuts one edge of the defect (**FIG 4**). A piece of sterile Esmarch bandage, aluminum foil, or DuoDerm can be used for the template.
- Such planning may lead to using other local flap rearrangement techniques to reduce the overall size of the defect, especially if it encroaches several different subunits.
- These measures can result in a smaller perforator flap with fewer demands on the donor site.
- The greatest degree of laxity is in the lower cheek and jowl area, which is the commonest site for flap harvest.

Positioning

- Smaller defects can be performed under local anesthesia with sedation, but it is more common to employ general anesthesia.
- A nasal or oral endotracheal tube can be used. It is best to secure this with suturing to the nasal septum or wiring to the dentition, to avoid tape and distortion to the perioral area to better appreciate the entire operative field to enable restoration of the best symmetry with the opposite side.

- The patient is supine and the operating table is turned 90 to 180 degrees away from the anesthesia team.

FIG 3 • **A.** Patient with full-thickness small cell carcinoma of the upper lip and nostril floor. **B.** Tailored full-thickness cheek perforator flap elevated. **C.** Flap inset onto defect.

FIG 4 • **A.** A patient with extensive defect involving the right upper lip, cheek, and alar base. **B.** Template of defect.

TECHNIQUES

■ Facial Artery Perforator Flap to Repair Perioral Defect

- After the flap is marked (**TECH FIG 1A**) and the artery and perforator are identified with Doppler, a small amount of local anesthetic with epinephrine can be injected along the proposed incision line (well away from the perforators) and allow it to take effect, to minimize oozing for the initial flap dissection.
- Incisions are made along the previously marked lines.
- Low-voltage needle-tip cautery (set at 15) helps precise dissection.
- Unlike some other perforator flaps in which the perforator is identified first, with the facial artery perforator flap (where there are multiple perforators along the course of the vessel), it is best to start the dissection at the distal end of the flap and carry the dissection down to the SMAS and muscle layer and start elevating just above the muscles. The terminal branches of the facial nerve are deep to the muscles and thus protected.
- The dissection continues toward the facial artery, which is easily visualized at the inferior, distal end of the flap.
 - The smaller distal perforators are cauterized and divided, and the flap is dissected superiorly toward the superior perforator (previously identified by Doppler).
- No attempt is made to skeletonize the pedicle, but the dissection is continued until adequate mobility is obtained to allow the flap to rotate into the defect.

TECH FIG 1 • **A.** Design of perforator facial artery flap. **B.** Elevated perforator facial artery flap. **C.** Postoperative appearance showing bulky flap that extends beyond natural subunits of the lip and cheek and loss of right alar base.

- Because the perforators are multiple and close together, there may be more than one perforator in the base of the flap. In addition, a cuff of soft tissue is needed for adequate venous drainage.
- The facial artery perforator flap (as compared with perforator flaps elsewhere) has the benefit of excellent tissue mobility and a tortuous facial artery, which allow more mobility without skeletonizing or thinning the flap excessively (**TECH FIG 1B,C**).

■ Secondary Revision Surgery

- Small defects can be repaired in a single stage, but larger defects may need secondary revision (**TECH FIG 2**).
- Even though one of the benefits of this type of flap reconstruction is the use of “like” tissue, it may still be bulky, and secondary debulking to restore the natural contour may be required.
- In addition, scars may need to be revised, and restoration of the normal subunits of the cheek, lip, and nose may require secondary surgery.

TECH FIG 2 • Secondary revision surgeries to restore right alar base (A) and natural contours of the lip and cheek (B).

PEARLS AND PITFALLS

Diagnosis and suitability of facial artery perforator flap

- Assess defect's suitability for a facial artery perforator flap based on its location and size. For larger flap requirements, there is a need to assess adequacy of donor site to avoid deformity or distortion. May need preliminary tissue rearrangement at the site of the defect to reduce its size and to conform to subunit principles of repair.

Flap vascularity

- Assess vascularity of facial artery and perforators with Doppler ultrasound.

Flap design

- Use templates to design flap.

Pedicle

- Select perforators that are closest to the defect to allow tension-free repair.

Technique	■ Mobilize flap as much as needed without skeletonizing the pedicle. Essential to leave a cuff of soft tissue for adequate venous drainage.
Secondary procedures	■ Inform patient of possible need of secondary procedures to improve the contour and restore appropriate subunits for best aesthetic result.

FIG 5 • The patient in TECH FIGS 1 and 2 at 19 months postoperatively.

POSTOPERATIVE CARE

- Bacitracin ointment is applied to the suture lines.
- Sutures are removed at 1 week.
- Normal smile function is restored once the swelling subsides.
- Revision surgery, as described above, can be undertaken at 2 to 3 months postoperatively.

OUTCOMES

- The facial artery perforator flap is a relatively new addition to our surgical armamentarium and has the benefit of allowing reconstruction with adjacent, “like” tissue, giving the best possible aesthetic outcome (**FIG 5**).
- Minor revisions to further enhance the aesthetic outcome are generally required.

COMPLICATIONS

- Venous congestion may occur if the flap is inadequately mobilized and rotated and sutured under tension.
 - This can be rectified by additional judicious pedicle dissection, enough to

allow tension-free rotation.

- If congestion persists, the flap should be returned to its bed and allowed to equilibrate.
- Venous congestion can also occur if the pedicle is thinned excessively.
 - This is more difficult to rectify and may need pricking and chemical leeching.
 - If a congested vein is present at the margin of the flap, this can be cannulated, and 0.5 cc of blood can be intermittently allowed to drain. This is more effective than simple pricking, as the whole venosome is decompressed. This technique can be used for any congested flap, and typically after a few hours, the venous drainage equilibrates.

40 Facial Artery Musculo-Mucosal (FAMM) Flap

CHAPTER

Julian J. Pribaz and Simon G. Talbot

DEFINITION

- The FAMM flap is an acronym for **f**acial **a**rtery **m**usculom**m**ucosal flap.
- It was derived based on the principles of combining a nasolabial and buccal mucosal flap, to create an intraoral axial flap, centered on the facial artery.¹
- It is very versatile and can be reliably based superiorly (retrograde flow) or inferiorly (antegrade flow), to reconstruct a wide variety of difficult defects within the oral and nasal cavities.

ANATOMY

- The FAMM flap is an axial flap containing the facial artery with its accompanying venous plexus, with a small amount of surrounding buccal fat, buccinator muscle, submucosa, and mucosa. It can be thought of as an intraoral and mirror-image version of an axial nasolabial flap.
- Arterial anatomy
 - The facial artery provides a rich blood supply to the lower central part of the face and neck.
 - It is a branch of the external carotid artery, and after giving off several cervical branches, it enters the face by hooking around the lower border of the mandible at the anterior edge of the masseter muscle (**FIGS 1 and 2**).
 - It follows a tortuous course through the cheek, passing upward and medially toward the oral commissure.
 - It traverses deep to the superficial muscles of facial expression—the risorius, the zygomaticus major and minor, and the superficial lamina of the orbicularis oris muscles.
 - It lies superficial to the buccinator, the levator angulioris muscle, and the

lateral edge of the deep lamina of the orbicularis oris muscle, and it has a variable relationship to the levator labii superioris muscle.

FIG 1 • Anatomy of facial artery.

- It gives off the inferior and superior labial arteries (through which it connects with the contralateral side), as well as multiple perforators to the cheek skin and mucosa. In the cheek, it also anastomoses with the buccal and transverse facial vessels.
- It continues superiorly as the angular artery, giving multiple perforators to the nasal alar and sidewall, and terminates near the medial canthus where it anastomoses with branches from the dorsal nasal, infratrochlear, and infraorbital vessels.²
- Venous Anatomy
 - The main facial vein does not run with the artery but is located more laterally in the cheek and approaches the facial artery near the angle of the mandible.
 - Nonetheless, the FAMM flap has an excellent venous outflow and rarely becomes congested due to a “syncytial” type of venous plexus within the submucosa, which connects not only to the facial vein but also to pterygoid plexus and maxillary vein.
- Due to its intraoral design, the FAMM flap spares the superficial and most important muscles of facial expression and their nerve supply, as well as the overlying skin, thus minimizing deformity.³
- The FAMM flap is usually 1.5 to 2 cm in width and can be 8 cm in length, but it is key that the facial artery traverses the entire flap. Although from the vascular point of view the flap could certainly be made wider, this would create

too large an intraoral defect, leading to contracture.

FIG 2 • Schematic of the course of the left facial artery through the cheek passing between the superficial muscles of facial expression and buccinators. Contralateral intraoral view of proposed right FAMM flap.

- The flap is designed anterior to Stensen duct.
- The FAMM flap can be based superiorly (where the blood flow is retrograde) or inferiorly (where the blood flow is antegrade), thereby increasing its versatility.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The FAMM flap may be indicated in patients with a wide array of relatively small (yet difficult to repair) defects and deformities within the oral cavity, including small defects in hard and soft palate, alveolus, buccal sulcus, floor of mouth, tongue, and tonsillar fossa. It can also be used to reconstruct defects of

the upper and lower lip vermillion. In addition, the flap has been used to reconstruct intranasal mucosal defects.^{4,5}

- The patient needs to be carefully evaluated and the problem in question accurately assessed according to its location and size to determine if a pedicled FAMM flap (with maximum size 2 × 8 cm) can be used for the reconstruction.
- An intact facial artery, detected by Doppler examination, is crucial, as is the lack of scars from previous procedures along the course of the flap.

Superiorly or Inferiorly Based FAMM Flap?

- A superiorly based FAMM flap is considered for defects involving the hard palate, upper alveolus, antrum, upper lip sulcus, and vermillion and for restoration of nasal lining (**FIG 3**).

FIG 3 • Superiorly based FAMM flap may be used to repair defects of (1) the hard palate, alveolus, (2) maxillary antrum, upper lip sulcus and vermilion, (3) nasal lining.

FIG 4 • Inferiorly based FAMM flap may be used to repair (1) floor of mouth, lower lip sulcus, and vermillion, (2) soft palate and tonsillar fossa, and (3) hard palate.

- An inferiorly based FAMM flap would be considered for defects in the floor of mouth, tongue, lower lip sulcus and vermillion, tonsillar fossa, and soft palate (**FIG 4**).

Intact Upper Jaw Dentition vs (Unilateral or Bilateral) Edentulous Alveolar Cleft Deformities?

- This will determine the type of FAMM flap that may be used; with an intact dentition, a superiorly based flap to repair a palatal defect cannot be used as the flap cannot traverse an intact dentition. However, it may be possible to repair a palatal defect with an intact dentition by using an inferiorly based flap, which is brought around the maxillary tuberosity.
- Reconstruction of fistulas and other through-and-through defects requires consideration of both lining and coverage requirements. The lining may be achieved with local turn-in flaps, but this may then make the defect too large for coverage with a FAMM flap. Occasionally, two FAMM flaps may be considered—one for lining and another for coverage.

SURGICAL MANAGEMENT

- Preoperatively, a careful assessment needs to be made whether the FAMM flap is appropriate for the needs of the repair based on the size and location of the defect within the oral or nasal cavity.
- A decision based on the problem being addressed will need to be made whether the FAMM flap will be superiorly or inferiorly based.
- Defects that are too large, or prior surgeries and scar, may preclude the successful use of the FAMM flap, and an alternative method of repair will be required.

Preoperative Planning

- It is essential to map out the course of the facial artery. The artery is easily palpated at the angle of the mandible, and then its course can be mapped out with a Doppler ultrasound, both extra- and intraorally.
- It is important to remember that the facial artery has a tortuous course through the cheek to allow for the tissue mobility for facial movement and expression.
- Its course is well anterior to the Stensen duct and has a roughly “boomerang-shaped” course, passing obliquely toward the oral commissure and then more vertically toward the alar base.

Positioning

- The procedure is performed under general anesthesia with the patient supine and the operating table rotated 90 to 180 degrees away from the anesthesia team.
- For intraoral work, a nasal endotracheal tube is best, but an oral endotracheal secured to the contralateral side of the mouth or with a Dingman retractor

securing the tube in the midline can also be used.

- Silk traction sutures are placed on the ipsilateral upper and lower lips and commissure (taking care not to injure the facial artery as it passes close to the commissure).
- The boomerang-shaped flap, which is 1.5 to 2 cm in width, is then marked out centered on the Doppler-identified facial artery.

Approach

- As previously mentioned, the selection of a superiorly or inferiorly based flap will depend on the problem at hand.
- Local anesthetic with epinephrine may be injected, but *only* into the distal part of the flap for easier dissection of the facial artery. Vasoconstriction should be allowed to take effect before commencing the flap dissection.

TECHNIQUES

- Dissection commences at the distal end of the flap, with an incision through the mucosa, submucosa, and buccinator muscle. The facial artery is identified, ligated, and divided. It is important that the facial artery itself and not a branch has been identified before proceeding with the rest of the flap harvest.
- It is helpful to leave the tie on the cut facial artery in the flap long and use it to apply traction to facilitate the dissection.
- The rest of the flap is then scored, and the dissection proceeds just deep to the facial artery, taking only a small cuff of buccinator and orbicularis oris muscles near the commissure.
- The flap is about 1 cm in thickness and contains the facial artery along its entire length, which designs a long axial flap with length/width ratios as high as 5:1.
- The flap dissection continues until an adequate length has been achieved (often 8–9 cm), and is either based superiorly or inferiorly, leaving a mucosal pedicle base to ensure adequate venous drainage.
- The facial vein is not seen in the dissection and hence not harvested with the flap. However, there is adequate venous outflow via an extensive submucosal venous plexus, and the flap does not appear congested.
- The arc of rotation for superiorly based flaps is at the gingivobuccal sulcus

and, for inferiorly based flaps, the retromolar trigone.

- **Superiorly based flaps** usually rotate 90 degrees when used for upper lip sulcus and vermilion reconstruction or to traverse an alveolar edentulous space to the palatal defect. It is preferable not to tunnel the flap but simply incise the mucosa from the base of the flap to the lip or palatal defect. The inset should be under no tension (**TECH FIG 1**).
- For nasal reconstruction, superiorly based flaps rotate 180 degrees and are tunneled through the gingivobuccal sulcus to the floor of the nose. To adequately inset these flaps into the nose, lateral rhinotomy incisions are required. Because of the bulk of the flap at its base, there will be temporary nasal airway obstruction, until the flap is divided and inset at 2 to 3 weeks.
- **Inferiorly based flaps** rotate at the retromolar trigone and may be used to repair tonsillar, floor of mouth, and tongue defects. They are also used to repair lower lip sulcus and vermilion. Again, it is best not to tunnel the flap, and it is safer to incise the mucosa between flap base and defect and inset the flap with no tension.
- When inferiorly based flaps are used to reconstruct posterior hard palate or soft palate defects, the bulkiness of the flap base may necessitate the use of a temporary bite block to prevent bite injury to the pedicle.
- A modification of the FAMM flap has been developed for use in palatal reconstruction where there is an intact dentition (precluding use of a superiorly based flap) and to avoid using a bite block with inferiorly based flaps. This involves the elevation of a mucoperiosteal palatal flap, which is the width of the FAMM flap and which is raised from the base of the FAMM flap as a turnover flap, which is dissected to approximately 8 mm of the palatal defect and used as a large nasal turn-in lining flap. Raising such a flap achieves two goals: providing nasal lining and creating a big enough trough to allow the FAMM flap to be inlayed, thus masking its bulky base and allowing a single-stage reconstruction without the need for a bite block.⁶
- The repair of the cheek donor defect is performed in layers, using absorbable sutures for the buccinator and mucosa (**TECH FIGS 2 and 3**).

TECH FIG 1 • Superiorly based FAMM flap for repair of a palatal fistula. **A.** A 15-year-old female with palatal fistula and alveolar gap. **B.** Design of superiorly based right FAMM flap. **C.** Elevated superiorly based FAMM flap. **D.** Repaired palate at 3 weeks.

TECH FIG 2 • **A.** Inferiorly based FAMM flap for repair of a large palatal defect. **B.** A 17-year-old male with large palatal defect and intact left dentition with no alveolar gap. **C.** Appearance of postinferiorly based FAMM flap—note the bulk at flap base requiring a bite block.

TECH FIG 3 • Inferiorly based FAMM flap used for the repair of palatal fistula. **A.** A 61-year-old female with palatal fistula post tumor excision. Note the intact dentition. **B.** Design of inferiorly based FAMM flap and anteriorly based mucoperiosteal palatal flap from base of FAMM flap to edge of defect. **C.** Mucoperiosteal palatal flap raised and used to repair nasal side of defect. **D.** Inferiorly based FAMM flap raised. **E.** FAMM flap inset.

PEARLS AND PITFALLS

Techniques

- It is essential to have the facial artery traverse the entire length of this long, thin flap to avoid ischemia at the distal tip and consequent failure of the reconstruction.
- Do not skeletonize the flap on the facial artery, as the venous drainage is by tiny venous plexus vasculature throughout the flap. It is important to leave some soft tissue around the base of the flap to ensure adequate venous drainage.
- Maintaining the proper plane of dissection should avoid injury to the branches of the facial nerve, whose terminal branches lie directly beneath the facial artery during the dissection, and they can be gently

dissected away from the artery.

Limitations

- A limitation to the FAMM flap is its size. Although larger intraoral cheek flaps can be designed on the facial artery, secondary donor-site problems such as cheek contractures may arise, so the use of flaps that are too wide should be avoided.

POSTOPERATIVE CARE

- It is essential to maintain good oral hygiene with regular mouth washes.
- The patient is commenced on a soft diet, which is advanced over the first week.
- The patient is counseled that there will be swelling in the cheek with some limitation of normal smile function. This is temporary and full and normal smile function returns once all swelling has subsided at 2 weeks.
- Any sutures that have not dissolved in the first 10 days can be removed.
- No special rehabilitation is required.

OUTCOMES

- The FAMM flap provides a versatile solution for a wide range of intraoral reconstructive needs.
- When based superiorly, the FAMM flap can be used to repair mucosal defects in the anterior hard palate, alveolus, maxillary antrum, nasal floor and septum, and upper lip sulcus, and vermillion.
- When based inferiorly, the FAMM flap can be used to close defects in the posterior hard palate, soft palate, tonsillar fossa, tongue, floor of mouth, lower lip sulcus, and vermillion.
- When used for palatal cleft defects, it eliminates the need for a palatal prosthesis.
- The base of the flap is thick, and when used for palatal, nasal, and alveolar defects, the flap base will need to be thinned or divided (which can be safely done at 2 weeks) and inset, to restore the nasal airway in cases of nasal lining reconstruction or contour restoration of the alveolus to allow dental rehabilitation.

COMPLICATIONS

- It is essential that the entire flap, especially its distal end, remains well perfused. This is the part which is most needed to complete the repair. This is achieved by ensuring maximum axi-ality with the facial artery running along the

entire length of the flap.

- With the use of larger flaps, the patients may experience some tightness and contracture at the donor site, requiring scar release with one or two Z-plasties of the contracted scar.

41 Free Flap for Hemi-Tongue Reconstruction

CHAPTER

Carrie K. Chu and Periong Yu

DEFINITION

- The tongue is a highly functional organ responsible for speech, deglutition, taste, and airway protection.
- Glossectomy defects following oncologic resection represent the most common indication for oral cavity reconstruction.
- Glossectomy defects can be partial, subtotal, or total. In general, defects that exceed one-third of the tongue or include significant floor of mouth resection usually require free flap reconstruction. Small defects may be closed primarily or skin grafted.
- Goals of partial glossectomy reconstruction include provision of soft tissue coverage, restoration of intelligible speech, restoration of oral intake, maintenance of patent airway, and separation of the oral cavity from the structures of the neck when required. Re-establishment of sensation is a secondary but important goal.

ANATOMY

- The tongue is composed of two anatomic components. The anterior two-thirds within the oral cavity is the oral (or mobile) tongue, whereas the posterior third within the oropharynx is the base of the tongue. The boundaries of the base of the tongue include the circumvallate papillae anteriorly, the glossoepiglottic folds laterally, and the vallecula and the lingual aspect of the epiglottis posteriorly (**FIG 1A**).
- General sensation to the anterior two-thirds of the tongue is supplied via the lingual nerve (CN V3). The chorda tympani (CN VII), which accompany the lingual nerve, are responsible for taste.

- Taste and sensation for the posterior one-third tongue derive from the glossopharyngeal nerve (CN IX).
- Motor innervation of the intrinsic and extrinsic tongue musculature is via the hypoglossal nerve (CN XII), with the exception of the vagus nerve (CN X) for the palatoglossus muscle. The floor of the mouth, the ventral sulcus, and the lateral gutter facilitate the excursion of tongue muscle for its intelligent functions. The tip of the tongue easily touches the palate for precise pronunciation (**FIG 1B**).
- The lingual arteries, branches of the external carotid artery, provide vascular supply to the tongue. A secondary blood supply arises from the tonsillar branch of the facial artery and the ascending pharyngeal artery. Venous drainage is via the lingual veins into the internal jugular vein.

PATHOGENESIS

- Oral cavity and oropharyngeal cancers, including squamous cell carcinoma and minor salivary gland carcinomas, are the main indications for hemiglossectomy.
- Risk factors for oral cavity and oropharyngeal cancers include tobacco and/or alcohol use, human papillomavirus infection, elderly age, male sex, inhaled environmental or occupational exposures, and poor oral/dental hygiene.

FIG 1 • A. Anatomy of the tongue. The tongue is composed of the anterior (mobile) tongue and the posterior base of tongue separated by the circumvallate papillae. **B.** The ventral sulcus allows the tip of the

tongue to touch the palate. The frenulum marks the midline of the ventral tongue. The lingual vessels travel on the ventral surface of the tongue and are close to the midline near the tip.

- Oral tongue cancers are typically treated with up-front surgical resection, whereas base of tongue cancers are frequently managed with neoadjuvant radiation followed by surgery as indicated.
- Glossectomy potentially compromises tongue function including speech, deglutition, and taste. The base of the tongue is more important for swallowing function, whereas the oral tongue is more important for speech and food manipulation. Restoration of these functions while preserving airway patency represents the main objective of hemiglossectomy reconstruction.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Symptomatology review should be performed including pain, swallow dysfunction, oral intake status, speech alteration, otalgia, paraesthesias, altered tongue mobility, and airway obstruction.
- History of neoadjuvant therapies should be noted. In cases of recurrence, records concerning prior surgical history, including neck dissection, should be reviewed in detail.
- The surgeon should be aware of factors that may compromise recipient vessel availability including radiation and prior cervical lymphadenectomy.
- Medical comorbidities and substance abuse history are both highly prevalent in this patient population.
- Occupation, hobbies, physical activity level, and hand dominance should be queried to select an optimal donor site.
- Head and neck examination should include the following elements:
 - Neck range of motion
 - Palpation of the facial artery
 - Quality of neck skin
 - Interincisal opening distance
 - Dental hygiene and presence of caries
 - Cranial nerve function (V, VII, XII)

IMAGING

- Computed tomography studies with contrast are reviewed for primary tumor dimensions including extension past midline, adjacent structures, and neck vessel patency.

SURGICAL MANAGEMENT

- Partial glossectomy defects smaller than one-third of the native tongue without a floor of mouth defect can typically be reconstructed with primary closure or skin grafting.
 - The latter may exhibit partial graft loss but ultimately will serve as a biologic dressing that allows for eventual mucosalization.
- Hemiglossectomy defects benefit from free flap reconstruction using a thin, pliable flap to avoid restricting functional tongue mobility.
 - These goals are distinguished from those associated with subtotal or total glossectomy, where the objective is to render a bulky flap reconstruction that provides adequate palatal contact to avoid aspiration and enhance speech intelligibility.
- Consideration should also be given to sensory reinnervation.
- Resection of the floor of the mouth combined with neck dissection creates a communication between the oral cavity and the neck along the lingual cortex of the mandible.
 - These defects, even if they involve less than one-third of the tongue, are best reconstructed with a flap to minimize the risk of infection and fistula formation, which can potentially delay crucial adjuvant therapy.
- The pectoralis major muscle or myocutaneous flap is a pedicled option for hemiglossectomy reconstruction. Its bulk, potential tethering and downward retraction are disadvantages for hemiglossectomy reconstruction. The functional outcomes are usually compromised.
 - Therefore, it is usually reserved for salvage after a failed free flap reconstruction or for use in high-risk cases deemed unsuitable for free flap reconstruction.

Preoperative Planning

- The potential functional impairment should be thoroughly discussed with the patient and family because these deficits will not only significantly affect their quality of life but their profession as well.
- Referral for dental extractions in preparation for flap inset and adjuvant radiation may be appropriate if significant caries or nonviable teeth are

identified.

- The availability of blood products based on preoperative type and cross should be confirmed.
- Potential donor-site assessment should be carried out including soft tissue thickness and quality of the upper extremity and thighs.
 - Hand dominance should be documented.
 - The radial and ulnar aspects of the forearm should be assessed for hair growth. A less hairy skin flap is preferred.
- Flap choices
 - In patients with very thin thighs, the anterolateral thigh flap is the first choice due to its minimal donor-site morbidity with the exception of young female patients.
 - Otherwise, the ulnar artery perforator flap is the first choice followed by the radial forearm flap as the ulnar artery flap creates a less conspicuous donor-site scar.
 - The most common flaps for hemiglossectomy reconstruction are described in this chapter, but consideration may be given to numerous alternative donor-site options that would provide thin, pliable tissue to meet the goals of reconstruction.
 - These include, but are not limited to, lateral arm, profunda artery perforator, anteromedial thigh, and medial sural artery perforator flaps.
- Preoperative nutritional status should be evaluated.
 - Some patients may have lost significant weight due to pain and inability to consume oral diet.
 - A percutaneous gastrostomy feeding tube may be necessary to provide adequate nutritional support before surgery.
- Antibiotic prophylaxis is administered before incision. For defects involving the aerodigestive track, 3 g of ampicillin/sulbactam is our antibiotic of choice, which is redosed every 6 hours.

Positioning

- The patient is placed in supine position, typically with the operating table reversed by 180 degrees.
- Placement of an underbody warmer avoids physical interference with multiple surgical sites.
- The dominant arm is tucked, while the contralateral potential donor arm is

prepped circumferentially toward the axilla.

- The arm is secured to the chest drapes to provide room for the extirpative team.
- It is then placed on an arm board for flap harvesting.
- The thighs are also prepared for potential thigh flap or as a skin graft donor site.
- The lower abdomen/groin may be prepared as a full-thickness skin graft donor site to cover forearm flap donor-site defect.
- A two-team approach is possible when harvesting a thigh-based flap.
 - With a forearm flap, flap elevation may require delay until the extirpative team completes the resection and neck dissection.

TECHNIQUES

■ Recipient Site Preparation

- While waiting for margins, the defect is assessed, and recipient vessels are dissected out.
 - A Dobhoff feeding tube is inserted into the stomach intraoperatively if percutaneous gastrostomy is not indicated.
- The length of the surgical defect is measured from the tip of the remaining tongue to the posterior limit, which can be in the base of the tongue or immediately above the epiglottis (**TECH FIG 1A**). In the latter case, there will also be a defect in the lateral pharyngeal wall.
- The viability of the remnant tongue should be assessed as well. However, any debridement should be conservative and limited to tissue that is definitively nonviable. Marginal areas may benefit from time for recovery and demarcation postoperatively.
- The width of the defect includes the tongue as well as the floor of the mouth. A flap width of 6 to 8 cm is usually required to adequately recreate the lateral sulcus and provide enough surface area coverage.
- A neck dissection is commonly performed along with a glossectomy.
 - Extra soft tissue is included in the flap design to obliterate any submandibular or upper neck dead space.
- The transected end of the lingual nerve should be explored for potential

sensory reinnervation (**TECH FIG 1B**).

- The lingual nerve is the optimal recipient for sensory reinnervation of the neotongue compared to other options such as the inferior alveolar nerve and the greater auricular nerve.
- It is usually 2 mm in diameter and can be found along the lingual cortex and anterior to the angle of the mandible.
- The lingual artery is often exposed and divided during glossectomy. With a diameter between 2 and 2.5 mm in most cases, the lingual artery represents an ideal recipient target.
- The facial artery is often divided as well during a neck dissection and can be used as a recipient artery. Its diameter is similar to that of lingual artery.
- The artery is dissected back to its origin from the external carotid artery and brought under the posterior belly of the digastric muscle (**TECH FIG 1C**), which can be divided if it facilitates improved vessel access.
- The curved portion of the artery is removed to allow for unimpeded inflow, leaving only a 1-cm stump on the external carotid artery.
- Sometimes, the lingual and facial arteries share a common trunk, which may be more suitable as a recipient vessel as the vessels may become small after the bifurcation. The superior thyroid artery is usually much smaller in Western populations and is usually undisturbed during ablative surgery, thus less desirable as a recipient vessel.
- The author's preferred recipient vein is a branch of or the common facial vein stump on the internal jugular vein depending on the flap vein size. A vein coupler or flow coupler is used for end-to-end anastomosis (**TECH FIG 1D**).

TECH FIG 1 • A. A hemiglossectomy defect can extend from the tip of the tongue to the base of the tongue, sometimes all the way to the epiglottis. The length of the defect usually varies from 6 to 12 cm. **B.** The transected lingual nerve (*white arrow*) can be found on the lingual surface of the mandible near the angle. The hypoglossal nerve (*yellow arrow*) can be found immediately below the digastric muscle. **C.** Common recipient vessels include the lingual artery, facial artery (*white arrow*), the common facial vein (*yellow arrow*), and its branches. **D.** A vein coupler is used for end-to-end venous anastomosis to a facial vein branch. **E.** An incision is made from the apron neck incision toward the midclavicle to explore the transverse cervical vessels. **F.** These vessels are immediately above the clavicle and have good size

match with the flap vascular pedicle.

- If no facial vein branches are available, an end-to-side anastomosis on the internal jugular vein itself is a viable option.
- If the internal jugular vein is also unavailable, the external jugular vein, if it remains in good condition, is the next choice.
- The transverse cervical vessels are usually available even in the vessel-depleted neck¹ and can be easily reached with a radial forearm flap or anterolateral thigh flap without the need for vein grafting (**TECH FIG 1E,F**).
- Finally, the internal mammary vessels and the use of a cephalic vein turn-up can serve as the last resort.

■ Flap Harvest

Radial Forearm Free Flap

- A flap with a width of 6 to 8 cm and length of 10 to 12 cm is usually required for a true hemiglossectomy defect.
 - The flap width is centered on the radial vessels with the distal margin at the wrist crease.
 - Flap elevation is performed under tourniquet control.
- The use of the venae comitantes as outflow is preferable to the cephalic vein,² because the distance of the cephalic vein from the radial artery may unnecessarily increase the flap width or the cephalic vein is positioned at the edge of the flap, not ideal as venous outflow (**TECH FIG 2A**).
 - In rare occasions, the venae comitantes of the radial forearm flap are inadequate. A small transverse incision at the wrist crease is made first to explore the venae comitantes (**TECH FIG 2B**). If one of these veins is at least 1 mm in diameter, the cephalic vein may safely be excluded.
 - Otherwise, the flap design is shifted laterally to capture the cephalic vein.
- Suprafascial dissection is preferable. The thenar branch of the superficial radial sensory nerve can be preserved with suprafascial dissection (**TECH FIG 2C**).
- At the midforearm level, the lateral antebrachial cutaneous nerve can be found near the midline. This nerve can be included in the flap for sensory reinnervation.

- In most hemiglossectomy cases, a small dead space is created under the mandible. Inclusion of some adipofascial tissue from the proximal forearm is useful to fill the dead space.
 - The proximal forearm skin flaps can be elevated below the subdermal plexus, leaving the subcutaneous tissue attached to the flap and the vascular pedicle (**TECH FIG 2D**).
 - Alternatively, this adipofascial flap can be based on a proximal perforator (**TECH FIG 2E**). This addition represents an important measure to decrease risk of infection and fistula formation.
- As the venae comitantes are usually no larger than 1.5 mm in diameter before they converge, the vein is usually taken above the convergence, where the diameter is usually greater than 2.5 mm.
- Once the flap and the vascular pedicle are completely dissected, the tourniquet is released to perfuse the flap and the hand for several minutes before dividing the pedicle.
- For donor-site coverage, a full-thickness skin graft from the groin area is preferred to split-thickness skin graft.
 - Suprafascial dissection and full-thickness skin grafting can achieve superior donor-site healing (**TECH FIG 2F**).
 - The hand and forearm are immobilized with a splint for 6 days.

TECH FIG 2 • A. The venae comitantes are preferred for venous outflow of the radial forearm flap. Using the cephalic vein may unnecessarily take a wider flap or render the cephalic vein along the edge of the flap. **B.** A small exploratory incision is made first at the wrist crease to ensure one of the venae comitantes is at least 1 mm in diameter for adequate venous outflow. **C.** Suprafascial dissection can avoid tendon exposure and preserve the thenar branch of the radial sensory nerve. **D.** For submandibular dead space filling, some adipofascial tissue is recruited from the proximal

forearm. **E.** This adipofascial tissue can also be based on a proximal perforator. **F.** With suprafascial dissection and full-thickness skin grafting following a radial forearm flap harvest, an excellent donor site can be achieved.

Ulnar Artery Perforator Flap

- The use of the ulnar artery perforator flaps creates a more favorable donor site compared with harvest of the radial forearm. It is also less hairy and slightly thicker but as pliable as the radial forearm flap.³ It has become the author's preferred flap for partial glossectomy reconstruction unless a very thin thigh flap is available.
- The pedicle length of the ulnar artery perforator flap is much shorter. The length of the radial forearm flap pedicle is not typically necessary for hemiglossectomy reconstruction unless the recipient vessels are the transverse cervical vessels, and the shorter pedicle length of the ulnar artery perforator flap may be desirable to avoid kinking.
- A line is drawn between the pisiform and the medial epicondyle, which corresponds to the septum between the flexor digitorum superficialis (FDS) and flexor carpi ulnaris (FCU) muscles in which the ulnar neurovascular bundle travels.
- The distal border of the flap is designed 5 cm above the wrist crease to avoid tendon exposure (**TECH FIG 3A**).
- Dissection is performed under tourniquet control.
 - The radial and distal borders of the flap are incised first.
 - Suprafascial dissection is performed toward the ulnar side until the perforators are seen emerging between the FDS and FCU muscles (**TECH FIG 3B**).
- The fascia over the FDS is then incised, and subfascial dissection is carried out (**TECH FIG 3C**). The perforators are small; thus meticulous dissection is required.
 - The locations of the perforators are marked on the skin surface with a 5-0 Prolene suture.
- The ulnar nerve travels with the vascular pedicle closely together for the majority of its length. The vascular pedicle is carefully separated from the

ulnar nerve, and retraction of the nerve should be avoided.

- One should never be rough to the ulnar nerve during dissection. Any traction should be applied to the vascular pedicle, not to the nerve.
- Small vascular branches to the neighboring muscles are clipped and divided.
- The use of electric cautery should be avoided as these vessels are very close to the ulnar nerve.
- Proximally, the vascular pedicle takes a turn radially away from the ulnar nerve (**TECH FIG 3D**).
- Several muscular branches are divided to reveal the bifurcation with the common interosseous artery.
- The median nerve and its branches can also be seen (**TECH FIG 3E**). Any traction to these nerves should be avoided.
- The venae comitantes usually do not converge, but each vein should have a diameter 2 to 3.5 mm, more than adequate for venous outflow.
- The authors use the venae comitantes exclusively instead of superficial veins and have not encountered any venous outflow issues.
- The medial antebrachial cutaneous nerve is included in the flap for sensory reinnervation (**TECH FIG 3F**).
- A small segment of the FCU muscle can be included for dead space filling if an adipofascial flap cannot be obtained in very thin patients (**TECH FIG 3G**).
- Once the vascular pedicle is isolated, the tourniquet is released to perfuse the flap and hand before dividing the vascular pedicle. Donor site care is the same as radial forearm flap.

TECH FIG 3 • A. The ulnar artery perforator flap is designed with the distal border 5 cm proximal to the wrist crease to avoid tendon exposure. **B.** Suprafascial dissection is performed ulnarly until the ulnar artery perforators emerging between the FDS and the FCU muscles are identified. **C.** The fascia is then incised; the subfascial dissection proceeds ulnarly to expose the ulnar neurovascular bundle. **D.** In the proximal forearm, the ulnar vessels (*yellow arrow*) take a radial turn away from the ulnar nerve (*white arrow*). The bifurcation of the ulnar artery with the common interosseous artery is then reached, which is the limit of the pedicle dissection. The median nerve and its branches can be seen at this level. Traction on the nerve should be avoided. **E.** The medial antebrachial cutaneous nerve (*yellow arrow*) can be included for sensory reinnervation. A small segment of the FCU muscle (*white arrow*) can be included for submandibular dead space filling if needed. **F.** A thin anterolateral thigh flap is another good option for hemiglossectomy reconstruction. **G.** Various amounts of vastus lateralis muscle can be included for dead space filling.

Anterolateral Thigh Flap

- In thin patients, the anterolateral thigh flap can also be used for hemiglossectomy reconstruction. Flap dissection is performed as previously described by the author.^{4–6}
- To fill the submandibular dead space, various amounts of the vastus lateralis muscle are included in the flap (**TECH FIG 4A**).
- Primary thinning of the flap periphery can reduce bulk for hemiglossectomy reconstruction.
- The lateral femoral cutaneous nerve of the anterolateral thigh flap can be

included for sensory reinnervation (**TECH FIG 4B**).⁷

- Additional thigh-based options including anteromedial thigh^{8,9} and profunda artery perforator flaps are feasible but generally too thick for hemiglossectomy reconstruction.

TECH FIG 4 • A. The lateral femoral cutaneous nerve (*arrow*) of the anterolateral thigh flap is used for sensory reinnervation. **B.** The harvested flap, showing with the vascular pedicle and lateral femoral cutaneous nerve (*yellow arrow*).

■ Flap Inset

- The distal end of the flap is oriented toward the tip of the remaining tongue.
 - The width of the distal flap lines up with the ventral surface of the remaining tongue from the tip to the frenulum attachment of the mandibular gingiva.
 - The two distal corners of the flap are anchored to these two structures, and the rest of the flap is draped over the glossectomy and floor of mouth defects toward the posterior limit of the defect.
 - Extra flap is trimmed to fit the defect.
- Flap inseting starts from the posterior end of the defect, either at the base of the tongue or above the epiglottis.
 - This part of flap inseting is completed through the neck exposure, before vascular anastomoses are performed.
 - Once flap inseting reaches the mandible, one can either proceed with vascular anastomosis or continue the inseting intraorally depending on the surgeon's preference and the ischemia time.

- Intraorally, one lateral edge of the flap is sutured to the gingiva and the other to the cutting edge of the remaining tongue.
- The key step in flap inseting is to recreate the ventral sulcus of the neotongue to avoid tethering.
 - The distal medial corner of the flap is sutured to the tip of the remaining tongue.
 - The distal cutting end (the width) of the flap is sutured to the ventral surface of the remaining tongue (**TECH FIG 5A**), thus creating a nice ventral sulcus and lateral gutter (**TECH FIG 5B**).
 - Great care should be taken not to catch the lingual vessels as they travel superficial and near the midline of ventral tongue (**TECH FIG 5C**).
- A single layer of interrupted 3-0 Vicryl sutures is preferred by the authors, although horizontal mattress sutures may be preferred by others in order to create a watertight seal.
 - It is important, however, not to tie the horizontal mattress sutures too tightly so as to avoid flap/mucosal edge necrosis leading to fistula formation.
 - When there is no gingiva left to attach the flap to, the flap can be sewn to the teeth by tying the suture knots around the teeth.
- Once the flap is partially or completely inset, the flap pedicle is brought under the mandible to the neck.
 - Meticulous care should be taken to avoid twisting of the pedicle.

TECH FIG 5 • A. The distal width of the flap is lined up with the ventral surface of the tongue to recreate the ventral sulcus. **B.** The rest of the flap is draped over the glossectomy and floor of mouth defect to recreate the lateral gutter. Both are important to prevent tethering. **C.** The adipofascial flap from the proximal forearm is just large enough to obliterate the submandibular dead space.

- When the lingual artery and common facial vein are used, the vascular pedicle is longer than needed.
- The pedicle should be carefully positioned with a gentle curve to avoid

kinking.

Sensory Reinnervation

- The cutting end of the lingual nerve is freshened, and the sensory nerve from the flap is coapted to the lingual nerve with several 8-0 nylon sutures.
 - This is usually done with loupe magnification, as the lingual nerve is inaccessible to the operating microscope.
 - Sensory recovery of the flap with this technique has been well documented, and therefore, sensory reinnervation is strongly recommended.
- After the vascular and nerve repairs are completed, the extra adipofascial tissue or muscle from the flap is carefully positioned to fill the submandibular space while avoiding pedicle compression (**TECH FIG 6**).

TECH FIG 6 • The reconstructed tongue should be able to lift and touch the palate without tethering. This is important to achieve intelligent speech.

■ Closure

- The oral cavity is irrigated with normal saline until clean.
- The neck wound is then irrigated with an ample amount of warm normal

saline, taking care not to squirt the saline directly on the vascular pedicle to avoid vessel spasm.

- Meticulous hemostasis is essential to avoiding a postoperative hematoma, which can compress the vascular pedicle. All areas should be carefully examined for hemostasis, especially in the neck dissection field, even if they have already been examined by the ablative surgeons.
- A 15 Fr Blake drain is placed in the neck, lateral to the internal jugular vein.
- At this point, the neck is slightly flexed (take out the shoulder roll and flex the neck to a neutral position), and the vascular pedicle is examined again.
 - Because the neck is usually hyperextended and turned to the opposite side during surgery, returning the neck to a neutral position can significantly change the position of the vascular pedicle, causing kinking or compression.
 - The pedicle is repositioned if necessary to avoid such problems.
- The neck incision is then closed.
- Finally, the reinforced tracheostomy tube is replaced with a no. 6 Shiley tube, if this has not been done already by the ablative surgeons.

PEARLS AND PITFALLS

Flap selection	■ Determine the goals of reconstruction based on extent of remaining native tongue. A hemiglossectomy defect should be reconstructed with a thin, pliable flap that will preserve mobility of the tongue remnant.
Avoid tethering	■ Adequate width of the distal flap (6 cm) is used to recreate the ventral sulcus, and the remaining flap width (6–8 cm) is used to recreate the lateral gutter. These steps are essential to avoid flap tethering that can significantly impair function. The patient should be able to lift the tip of the tongue to touch the palate after hemiglossectomy reconstruction (FIG 22).
Flap inset	■ Inset is mostly performed before microsurgical anastomoses to limit soft tissue swelling and bleeding. ■ Circumdental sutures can be used if remnant gingiva is inadequate.
Closure	■ Discontinue neck hyperextension, and restore neutral positioning prior to neck closure to ensure the absence of pedicle kinking.

POSTOPERATIVE CARE

- In most cases, patients may be awakened from general anesthesia and transferred to the surgical floor for flap monitoring.
- The traditional convention of intensive care monitoring with prolonged sedation and/or mechanical ventilation for head and neck reconstruction is unnecessary unless medical indications arise. This approach significantly expedites recovery and reduces cardiopulmonary morbidity.
- Pulmonary toilet is improved with spontaneous respiration, and the hemodynamic lability associated with continuous sedation is avoided.
- Flap monitoring regimens are surgeon dependent, but the authors practice hourly clinical examination of the intraoral flap for the first 48 hours as the standard.
- Pencil and/or implanted Doppler are used to supplement the monitoring regimens as available or required.
- Flap assessment is reduced to every 2 hours subsequently for the next 48 hours and to every 4 hours thereafter.
- Delirium tremens prophylaxis should be given to patients with history of alcohol abuse, which is prevalent among head and neck cancer patients.
- History of substance abuse and narcotic dependence may predispose patients to postoperative confusion and agitation and may lead to hypertension, hematoma, anastomotic breakdowns, and avulsion of the vascular pedicle. Prompt management of these issues with neuropsychiatric staff is important.
- Enteral tube feeding is initiated on postoperative day 1.
- Patients are allowed to mobilize starting on postoperative day 1 and ambulating by postoperative day 2.
- Broad-spectrum antibiotics such as ampicillin/sulbactam are usually continued for 3 days or longer, as indicated.
- A modified barium swallow study is performed by speech pathology typically on postoperative day 7 to evaluate for swallow function, leak, and aspiration.
- In patients with no leaks or aspiration, a liquid diet is started and then quickly advanced to a soft or regular diet as tolerated. If the patient received previous radiation, the swallow study may be deferred to 2 weeks after surgery.
- Patients are typically discharged between postoperative days 5 and 7.
- Oral hygiene is critical. Patients should rinse frequently with saline or Peridex until the flap is well healed.
- In patients with leaks or aspiration upon swallowing, oral intake is withheld,

and a modified barium swallow study is repeated in 2 weeks or longer, as clinically indicated.

- Tracheostomy downsizing, capping, and decannulation can be performed if clinically tolerated once acute postoperative surgical site swelling is diminished prior to discharge.
- In high-risk patients, delayed decannulation or long-term tracheostomy dependence may be indicated.
- Outpatient follow-up with speech therapy to improve swallow and speech function is beneficial.

OUTCOMES

- The most important predictor of functional outcome is the extent of remaining tongue. Good clinical and functional outcomes following hemiglossectomy reconstruction have been reported.^{10–12}
- Speech intelligibility after hemiglossectomy reconstruction has been studied using a standardized numeric speech therapy scale (4, greater than 80% intelligible; 3, 50%–80% intelligible; 2, less than or equal to 50% intelligible; 1, unintelligible; and 0, inability to speak). Patients who underwent partial glossectomy or hemiglossectomy had significantly superior speech function (mean scores 3.59, 3.74, respectively) compared with patients with subtotal glossectomy (3.14) or total glossectomy (2.42).
- Successful sensory reinnervation of the radial forearm flap has been well documented.^{13,14} Innervation was associated with better speech scores following hemiglossectomy reconstruction (3.89 vs. 3.42).
- Risk factors for poor swallowing function after glossectomy include age of 60 years or older and preoperative radiation.
- Swallow function after hemiglossectomy reconstruction has been evaluated based on type of diet tolerated (4, regular unrestricted diet; 3, soft diet; 2, pureed or liquid diet; 1, oral diet requiring tube-feed supplementation; and 0, tube-feed dependency).
- Patients who underwent more extensive resections (total glossectomy, 0.83; subtotal glossectomy, 1.49) had significantly worse swallow function than did those who received only a partial glossectomy or hemiglossectomy (2.47).
- Patients who received innervated flaps had superior swallowing outcomes compared with patients who received noninnervated flaps in our experience, but controversy exists surrounding this topic in the surgical community.

COMPLICATIONS

- In the authors' published experience, the overall 30-day complication rate following microsurgical reconstruction for glossectomy was 23.6%. Total flap loss rate was less than 1%.
- Potential complications include the following:
 - Flap arterial or venous thrombosis
 - Partial or complete flap loss
 - Bleeding or hematoma
 - Infection or abscess
 - Flap dehiscence
 - Orocutaneous fistula
 - Respiratory complications including pneumonia
 - Aspiration
 - Altered or poorly intelligible speech
 - Inability to swallow or tolerate oral intake, feeding tube dependence
 - Tracheostomy dependence
 - Flap donor-site complications (skin graft failure, seroma, paraesthesia, etc.)

42 Floor of Mouth Reconstruction

CHAPTER

George N. Kamel, J. Alejandro Conejero, and Evan Garfein

ANATOMY

- The floor of mouth is a U-shaped mucosal structure covered by squamous mucosa that is bordered by the alveolar ridge of the mandible and extends posteriorly to the anterior tonsillar pillar (**FIG 1A**).
- Medially, the floor of the mouth (FOM) merges with mucosal, ventral surface of the tongue to the level of the frenulum, which divides the floor into two oval spaces.
- The FOM contents include the sublingual salivary glands, submandibular ducts, oral component of the submandibular salivary gland, the geniohyoid and genioglossus muscles, and the lingual and hypoglossal nerves.
 - The lingual nerve provides sensation to the FOM.
- The arterial supply to the FOM is from the lingual arteries, branches of the external carotid artery, as well as the mylohyoid and submental branches of the facial arteries.
- The mylohyoid and hypoglossus muscles provide both structural support to the contents of the FOM and serve as barriers to the submental and submandibular triangles of the neck (**FIG 1B**).
- The sublingual salivary glands, located beneath the mucosa of the anterior FOM, drain via the excretory ducts of Rivinus, which drains into the submandibular duct or directly into the FOM through the plica fimbriata (mucous membranes located on either side of the frenulum).
- The anterior FOM lymphatic drainage is to the submental and submandibular nodes, whereas the posterior FOM drains to the upper cervical lymph nodes.

PATHOGENESIS

- Floor of mouth squamous cell carcinoma (SCC)
 - Approximately 18% to 45% of all oral SCCs occur in the FOM, and most originate at the anterior midline.¹ As with other locations of oral SCCs, there is a strong association with alcohol consumption and tobacco smoking. There is an increasing incidence of HPV-associated head and neck SCCs in patients without traditional risk factors.
 - SCC tumors typically spread in a superior or horizontal fashion as the muscular floor of the FOM serves as a barrier to tumor spread. However, these tumors can also invade the submucosa, the intrinsic tongue muscles, and the contralateral space in the FOM.
 - The location of FOM structures and their association with the tumor affects the presentation of tumor invasion. In certain cases, SCCs may obstruct the ostia of the submandibular duct, which is located along either side of the frenulum resulting in inflammatory changes and ductal dilatation. In contrast, the sublingual glands are more prone to direct invasion due to proximity of the tumor. Invasion of the mandible upstages the tumor.
 - Cervical lymph node invasion is common at time of diagnosis, and hematogenous spread to distant sites including the liver, bones, and lungs must be ruled out.
- Floor of mouth salivary gland tumors and sarcomas
 - These tumors account for 3% to 5% of all head and neck cancers, most commonly appearing in the sixth and seventh decade of life.

FIG 1 • Anatomy (A) and musculature (B) of the FOM.

- The etiology is multifactorial; however, occupations with an associated increased risk include mining, asbestos exposure, and rubber manufacturing.
- The most common of these tumors are adenoid cystic carcinoma and mucoepidermoid carcinoma.
- Most patients present with a painless slow-growing mass. Others may manifest with perineural invasion resulting in pain or numbness.
- Sarcomas of the oral cavity most often arise from the maxilla or mandible as an osteosarcoma, chondrosarcoma, rhabdomyosarcoma, or liposarcoma. Liposarcomas occur with equal frequency in the mandible and maxilla. Similar to other neoplasms of the oral cavity, surgical resection is the primary modality for treatment.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient history begins with a thorough assessment of the onset of symptoms, duration, course, and associated risk factors, the most common of which are alcohol consumption and tobacco use.
- Symptoms of floor of mouth tumors may include an enlarging or recurrent mass, difficulty with speech, chewing or deglutition, odynophagia, halitosis, and red or white intraoral discoloration.
- The physical exam begins with inspection and palpation of both the extraoral and intraoral soft tissues. This includes assessment of the lips, intraoral labial mucosa, buccal mucosa, the dorsal and ventral surface of the tongue, the hard palate, and the FOM.
- The sublingual, submandibular, and parotid glands are palpated and examined for any abnormalities.
- The neck is inspected for signs of cervical lymphadenopathy as floor of mouth cancers typically metastasize to the cervical chain of lymph nodes. Evaluation of the anterior deep cervical lymph nodes, the preauricular and postauricular lymph nodes, is included in the examination.

IMAGING

- Numerous imaging modalities are available for both diagnostic as well as treatment planning and include plain radiographs, magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET).
- Plain radiographs or panoramic images are routinely used by dentists and may initially suggest a malignant lesion during an initial evaluation. CT scans, however, are currently the standard for primary tumor detection with a

specificity ranging from 81% to 100% and sensitivity of 41% to 82%.

- PET scan or PET/CT evaluates tissue metabolic activity and is used to assess for metastatic spread to lymph nodes as well as distant tissues.

SURGICAL MANAGEMENT

- Successful reconstruction after oncological extirpation is based on the following principles:
 - Tumor-free resection margins
 - Maximizing mobility of the remaining tongue
 - Watertight closure and seal that protects the neck structures from FOM secretions
 - Maintaining mandibular continuity
- Reconstructive options
- FOM defects arise most frequently from composite resections of the mandible and FOM or tongue and FOM. Less frequently, resection of soft tissue tumors or salivary gland cancers leads to isolated FOM defects.
- Many options exist for reconstruction of the soft tissue FOM defects. In general, the reconstructive options are dictated by the volume and type of tissue that is resected. Thus, soft tissue low volume defects require replacement with low volume soft tissue flaps. Large-volume composite defects that include soft tissues and bone may require reconstruction with osteocutaneous flaps. Rarely, complex cases may require more than one flap for reconstruction; however, in general, most defects of the FOM can be reconstructed with a single flap.
- Microvascular free flaps are the preferred reconstructive options for patients with floor of mouth defects because they have excellent blood supply; can be constructed of thin, pliable tissue; and can be customized to fit any defect.
- Soft tissue flaps such as the radial forearm, anterolateral thigh (ALT), medial sural artery perforator flap (MSAP) and pectoralis major musculocutaneous flaps are most commonly used for FOM reconstruction. The selection of reconstructive technique depends on patient factors, the extent and complexity of the surgical resection, and surgeon preference.
 - Patient factors include thickness of the subcutaneous fat layer in the flap donor sites and blood supply/circulation (eg, intact palmar arch).
 - Surgical factors include primarily the type and extent of resection. For example, complex defects that include wide resection of the FOM musculature and supporting structures may require a large volume composite

flaps that include skin and muscle to obliterate dead space, whereas low-volume defects restricted to the FOM mucosa may be better reconstructed with thin pliable flaps.

- Ultimately, the flap that is selected for reconstruction should maximize reconstructive goals of obtaining a watertight closure of the defect and maximize the potential to swallow and speak.

Soft Tissue Flap Options

- Radial forearm fasciocutaneous free flap
 - The radial forearm flap was first described by Yang in 1981 and later popularized by Soutar and McGregor in 1986 for intraoral reconstruction and is a skin and fascial flap based on the radial artery, its venae comitantes, and, often, the cephalic vein.²
 - It is considered the workhorse for many soft tissue head and neck defects and is adequate for moderate to large FOM defects.
 - It is pliable, thin, and has a long vascular pedicle measuring (10–15 cm). One may incorporate a portion of the radius bone or palmaris tendon if needed for reconstruction.
 - The superficial branch of the radial nerve lies adjacent to the radial artery, and this branch supplies sensation to the dorsal aspect of the thumb and index finger. This branch should be preserved during dissection of this flap.
 - The skin paddle of the radial forearm flap is supplied by fasciocutaneous branches of the radial artery, with venous drainage through the superficial cephalic vein and the deep venae comitantes.
 - Sensory innervation to the FOM can be restored in some cases by anastomosing the lateral antebrachial cutaneous nerve in the flap to the lingual or inferior alveolar nerves in the recipient site.³
 - The anatomical location of the radial forearm flap allows for simultaneous harvest by the reconstructive team at the time of tumor extirpation.
 - Disadvantages of the radial forearm flap include decreased circulation to the hand, risk of tendon exposure, radial nerve injury, painful neuroma, cold intolerance, and possible poor cosmetic result.
- Anterolateral thigh flap
 - The ALT flap, first described by Song in 1984 and further advanced by Wei, is a soft tissue perforator flap based on the descending branch of the lateral circumflex femoral artery (DLCFA), the largest branch of the profunda femoris.^{4,5}

- The ALT flap has a long pedicle, ranging from 7 to 16 cm with reliable septocutaneous or musculocutaneous perforators arising from the descending branch of the LCFA.
- The location of the flap allows for simultaneous harvest at the time of tumor extirpation.
- The ALT flap has minimal donor site morbidity as one of its principal advantages and is an optimal choice for large volume complex defects of the FOM because it can be harvested with vascularized fascia and muscle if necessary.
- Disadvantages to the ALT flap include variable anatomy and location of the perforators. It should be avoided in small intraoral defects due to the potential increased bulk of this flap.
- Medial sural artery perforator flap
 - The MSAP flap was first described by Cavadas in 2001 for reconstruction of distal limb defects. In 2008, Chen introduced the MSAP free flap for intraoral reconstruction following cancer ablation.⁶
 - The MSAP flap is, in most patients, thin and pliable, suitable for intraoral defects.
 - The MSAP flap is associated with minimal donor site morbidity, and its locations allow for simultaneous harvest at the time of tumor extirpation.
 - The disadvantage of the MSAP flap is in the difficulty of identifying a reliable cutaneous perforator that may at times be mistaken for a muscular branch of the medial sural vessels.
- Pectoralis major musculocutaneous flap
 - The pedicled pectoralis major musculocutaneous flap first described by Ariyan in 1979 was considered the workhorse for oropharyngeal defects prior to the advancements made in free vascularized tissue transfer.⁷
 - The pectoralis major musculocutaneous flap is now most often used as a salvage flap in FOM reconstruction. The pectoralis major musculocutaneous flap is also useful in patients who are poor candidates for vascularized free tissue transfer or those with large defects who require two flaps for reconstruction.
 - The disadvantages include a contour defect, slight loss of arm adduction and rotation provided by the pectoralis major muscle, and added bulk in the neck caused by the pedicled muscle.

TECHNIQUES

■ Floor of the Mouth Reconstruction With a Radial Forearm Free Flap

Preparation of the Recipient Site

- The defect is carefully analyzed to understand the extent of the resection and the tissues necessary for reconstruction.
 - Specifically, attention is paid to the extent and pattern of mucosal defect as well as the volume of the defect created by resection of the FOM musculature/soft tissues (**TECH FIG 1**).
- If a microvascular free flap is planned, recipient vessels in the neck are identified, dissected, and made ready for microvascular anastomosis.
 - In patients who have had a previous neck dissection or radiation therapy, assessment of arterial inflow should be done. In most cases, however, the quality and patency of the vessels are easily assessed during the dissection.

TECH FIG 1 • Floor of mouth defect after partial tongue, FOM, and marginal mandibulectomy.

- If the resection is limited to the FOM mucosa, a tunnel is created in the FOM musculature to enable passage of the flap pedicle to the recipient vessels.
 - The tunnel should be large enough to account for postoperative swelling, thus avoiding vascular compression.
 - Hemostasis should be meticulously maintained because bleeding after pedicle transfer is difficult to control.

Flap Dissection

- Prior to the radial forearm free flap harvest, an Allen test using a pulse oximeter placed on the thumb with concomitant occlusion of the radial artery is performed to assess for blood flow between the superficial and the deep palmar arch systems.
- An appropriately sized skin paddle is designed based on the radial artery approximately 1 cm proximal to the wrist crease and, in most cases, including the cephalic vein (**TECH FIG 2A**).
- The forearm is exsanguinated, and a sterile tourniquet is insufflated to 200 to 250 mm Hg.
- An incision is then made through the subcutaneous tissue outlining the skin paddle and extending proximally toward the antecubital fossa.
- The dissection continues on the radial aspect of the flap, first identifying the cephalic vein and dissecting it out proximally and ligating the distal end.
- Next, the brachioradialis fascia is identified, and a subfascial dissection is performed taking care to preserve the paratenon of the brachioradialis tendon and preserving communicating venous branches of the cephalic vein. The superficial radial nerve is identified at the distal aspect of the dissection and is preserved.
- The dissection continues in an ulnar direction toward the palmaris longus and flexor carpi radialis (FCR) tendon in a subfascial plane, with care not to injure the paratenon of the FCR tendon. The pedicle is identified between the muscle bellies of the FCR and brachioradialis muscles.
- The distal ends of the radial artery, venae comitantes, and cephalic vein are identified, ligated with surgical clips, and divided.
- The radial forearm flap is then elevated off the flexor digitorum superficialis and flexor pollicis longus muscles toward the antebrachial fossa.
- The tourniquet is released, and hemostasis is ensured.
- Perfusion to the hand/thumb is verified, and the flap is allowed to reperfuse prior to division of the vascular pedicle (**TECH FIG 2B**).

- The donor site is then closed in a layered fashion, and a split-thickness skin graft is applied.

Flap Inset

- The flap vessels are marked with methylene blue or a marking pen to maintain correct orientation and ligated (**TECH FIG 3A**).
- The flap is transferred to the head and neck area, and the pedicle vessels are passed through the FOM defect (or tunnel) to the recipient vessels taking care to avoid twisting or kinking of the pedicle.
 - This may be facilitated by using a Penrose drain passed through the tunnel to transfer the pedicle to the recipient site.
- The flap skin is inset into the defect using 2.0 Vicryl sutures in an interrupted fashion sutured to the remaining FOM mucosa. The inset begins at the deepest/least accessible portion of the FOM and proceeds toward the most accessible area (**TECH FIG 3B**).
- In some cases, there is insufficient mucosa available to suture to the flap.
 - In these cases, it is important to make sure that the flap is securely inset; otherwise, postoperative dehiscence and leak may occur. This is best accomplished by suturing the flap using a U-shaped stitch around the teeth.
 - The needle is passed through the gingiva distal (ie, behind) a tooth toward the intraoral defect. The suture is then passed through the skin entering the subcutaneous layer (ie, from deep to superficial). The needle is then passed through the flap skin through the skin in a U-shaped manner and then passed through the gingiva mesial to the tooth. The suture is tied around the tooth securely holding the flap in place (**TECH FIG 3C,D**).
- In most cases, most/all of the inset is performed prior to microsurgical anastomosis to ensure that the position of the pedicle does not change after inset.
 - In some cases, the flap is partially inset, microsurgery is performed, and the flap is then cut to final size and inset. However, usually with careful planning, minimal alteration of the flap is necessary.

TECH FIG 2 • **A.** Preoperative markings of a radial forearm flap. **B.** Radial forearm flap elevated on radial artery/vein and cephalic vein.

TECH FIG 3 • **A.** Radial forearm flap ligated and pedicle marked with *blue ink* to prevent kinking/twisting. Lateral antebrachial cutaneous nerve is shown (*arrow*). **B.** Final inset of the flap achieving a

watertight closure. **C,D.** Sequence of tying U-shaped suture around teeth to secure flaps in cases with inadequate remaining mucosa for flap suturing so that the knot is on the mandible side.

PEARLS AND PITFALLS

Indications	■ When reconstructing FOM defects, the goals of reconstruction are to maximize tongue mobility and maintain a watertight closure to prevent leaks.
Advantage	■ Microvascular free flaps are the preferred reconstructive options for patients with floor of mouth defects after tumor extirpation due to a more robust blood supply, flexibility in donor site harvest, and positional customization.
Approach	■ The defect should be carefully analyzed such that the right flap is selected. This decision is influenced by the volume of the defect, concomitant structures that may be involved, recipient vessels, and patient factors. ■ Care should be taken in flap design so that minimal alteration of the flap is necessary during inset if possible. ■ The flap should be securely inset to avoid dehiscence. If there is insufficient mucosa available to suture the flap, then sutures should be placed around the teeth.

POSTOPERATIVE CARE

- Patients are typically kept on bed rest for 12 to 24 hours postoperatively with the head of bed elevated to 30 degrees to minimize postoperative edema.
- Patients who undergo free flap reconstruction are monitored closely in the postoperative period using physical exam, use of transcutaneous Doppler probe, implantable Doppler probe, or combination thereof.
- Patients are treated with aspirin and/or Lovenox or subcutaneous heparin for deep venous thrombosis prophylaxis (unless otherwise contraindicated). Sequential compression devices are also utilized while the patients are on bed rest.

- Perioperative antibiotics targeted against intraoral microbial flora are maintained for 72 hours.
- Antibiotics may be necessary for longer periods of time in patients with contaminated wounds or those with severe tissue damage (eg, extensive surgery with or without radiation) or those with comorbid conditions (eg, poor dentition, obesity, uncontrolled diabetes, history of alcohol use).
- Enteral nutrition via feeding tube is started 24 hours postoperatively, and a speech and swallow evaluation is typically obtained by 7 to 14 days postoperatively.
- Patients are evaluated by physical therapy while in the hospital and are transitioned to either home or a rehabilitation facility upon discharge.

COMPLICATIONS

- Short-term postoperative complications may include bleeding, dehiscence, or flap failure from arterial/venous thrombosis.
- Long-term complications may include flap failure, salivary fistulas, wound dehiscence, or radiation-induced fibrosis yielding insufficient soft tissue to accomplish reconstructive goals.

43 Reconstruction of Total Glossectomy Defects

CHAPTER

Mark Sisco and Mihir Bhayani

DEFINITION

- Total glossectomy defects occur most commonly in patients with malignancies of the tongue or floor of mouth.
- These complex defects require reconstruction with moderate to large volume flaps to restore the bulk of the tongue.
- Because the muscular action of the tongue is not restored by this procedure, the bulk of the reconstructed tissue is necessary for swallowing (by pushing the food to the back of the mouth). However, restoration of swallowing is not always feasible and depends on the amount of residual normal tongue base and floor of mouth that is preserved.

ANATOMY

- The oral cavity comprises the floor of mouth, oral tongue, alveolar ridge, buccal mucosa, and hard palate.
- The tongue itself is composed of intrinsic striated muscles that affect its shape. Extrinsic muscles, including genioglossus, hyoglossus, palatoglossus, and styloglossus, insert into the tongue and affect its position in the oral cavity.
- The blood supply to the tongue is almost entirely derived from the lingual arteries, which arise from the external carotid arteries.
- The base of tongue, which represents the posterior third of the tongue, is attached to the hyoid bone and represents the anterior-most portion of the oropharynx.
- The floor of mouth is the U-shaped mucosal reflection that spans the region between the mandibular alveolus and ventral tongue.
- The tongue has distinct functions to support mastication, deglutition,

sensation, and speech.

- For mastication, it moves food into position for chewing.
- During deglutition, the tongue propels the food bolus posteriorly into the oropharynx by progressively pressing against the hard palate in a retrograde fashion. This is followed by contraction of the palatoglossus muscles and elevation of the base of tongue. From this point onward, coordinated contraction of muscles in the pharynx and hypopharynx moves the bolus into the esophagus.
- The tongue is the most important articulator of speech and is critical to the production of all vowels and several consonants.

PATHOGENESIS

- Over 95% of tongue cancers are squamous cell carcinomas.
 - It is more common in males and often presents in the fifth and sixth decades of life.
- The most common etiology is smoking and chewing tobacco.
- Human papillomavirus has emerged as a new cause of base of tongue malignancies that arise from the lingual tonsils.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with tongue cancer who present to the plastic surgeon have been determined to need resection of at least 25% of the tongue.
- Total glossectomy generally refers to removal of at least 75% of the tongue.
- Patients should be queried about a history of carotid disease, smoking, prior surgery, or radiation therapy.

IMAGING

- Patients who have a history of prior neck lymph node dissection or known carotid disease may benefit from angiography to determine optimal management.

SURGICAL MANAGEMENT

- The goals for reconstruction are as follows:
 - To enable complete resection of the tumor with wide margins
 - To achieve wound closure
 - To minimize donor morbidity
 - To restore function
- In the case of the total or subtotal glossectomy, these goals are best

accomplished by providing a reconstruction that minimizes dead space and provides bulk.

- This will reduce the likelihood of aspiration and provide a platform for food boluses during swallowing.
- If patients present with aspiration, the surgeon should plan for total laryngectomy at the time of total glossectomy.
- In general, the above goals are best met with microvascular transfer of a vertical rectus abdominis myocutaneous (VRAM) or anterolateral thigh (ALT) perforator flap. Pedicle flaps, such as the pectoralis myocutaneous flap, may be used but do not provide as much bulk or freedom in inset.

Preoperative Planning

- Potential donor sites should be examined, including the ALT and abdomen.
 - A determination of the donor site should be based on surgeon preference as well as the body habitus of the patient.
 - Patients who have had previous abdominal surgery or who have a large abdominal pannus may not be good candidates for a rectus-based flap.
- Patients should generally have gastrostomy tubes placed preoperatively or at the time of surgery.
 - If laryngectomy is not planned, patients should also have tracheostomy tube placed to secure the airway.

Positioning

- A shoulder roll should be used to extend the neck.

TECHNIQUES

■ Anesthesia and Assessment of the Defect

- After anesthesia is initiated, the oral cavity and oropharynx are examined to assess the anticipated defect (**TECH FIG 1**).
- Tracheostomy is usually performed first, followed by glossectomy and then neck dissection as indicated.
- In cases in which a total glossectomy is known to be required, a two-team approach can be used to reduce surgery time.

- For total glossectomy defects, the primary goal is to create enough bulk anteriorly to allow contact between the flap and the hard palate when the mandible is closed.

TECH FIG 1 • Total glossectomy defect with preservation of a small portion of the right floor of mouth using a visor incision.

- If necessary, the flap may be folded upon itself to increase its bulk.

■ Flap Selection and Harvest

- A soft tissue flap with sufficient bulk and volume is selected. Most commonly, the VRAM flap or the ALT flaps are used since these flaps provide both skin and healthy muscle with sufficient bulk to reconstruct the missing tongue. In general, thinner fasciocutaneous flaps such as the radial forearm are less useful due to insufficient volume.
 - In this example, a musculocutaneous ALT flap was selected (**TECH FIG 2A,B**).
- Other myocutaneous flaps or fasciocutaneous flaps such as the gracilis or parascapular flap (with or without latissimus muscle), latissimus flap, etc. are

used less frequently.

- Recipient vessels are dissected in the head and neck area and made ready for microanastomosis.
- The flap is transferred to the head and neck area and inset into the defect using interrupted 2-0 braided absorbable sutures. This ensures tension-free inset and minimizes the risk of inadvertent flap avulsion of the anastomosis (**TECH FIG 2C**; Videos 1 and 2).

Video p3-c043_01

Video p3-c043_02

- The flap may also be neurotized by connecting the remnant of the lingual nerve (if preserved) to a cutaneous branch of the ALT flap (**TECH FIG 2D**). This is usually easiest to do before inseting the skin paddle for the flap.

TECH FIG 2 • A. Skin markings for anterolateral thigh myocutaneous flap. **B.** Harvested flap showing the skin and muscle portion. In these cases, it is best to keep the muscle and skin connected. **C.** Flap inset begins in the deepest portion of the defect with interrupted Vicryl sutures. **D.** Anastomosis of the lingual nerve to the cutaneous nerve of the flap can be performed if this nerve is preserved during the resection. This is most easily accomplished prior to inset of the skin paddle.

■ Flap Inset

- Flap inset begins by passing the flap vessels into the neck and inset of the deepest/most dependent portion of the flap. The inset then progresses proximally, rolling the tissue inward to increase the bulk of the flap in the oral cavity.
- The vascular anastomoses are performed to high-flow vessels. These are most commonly the facial artery and common facial vein; however, the lingual or other arteries may be used.

- The venous anastomosis should be under sufficient tension to prevent kinking with neck motion. I prefer to use a microvascular coupler to a short branch from the internal jugular vein.
- Alternatively, an end-to-side anastomosis may be performed to the internal jugular vein. This requires the use of a small Satinsky clamp.
- Completion of the inset is performed, again using interrupted 2-0 braided absorbable sutures (**TECH FIG 3A**; Video 3).

Video p3-c043_03

- The muscle from the flap can be used to reconstruct the floor of mouth and sutured loosely to the mandible on each side (**TECH FIG 3B**). This is helpful to prevent leaks (or to contain them if they occur).
- A 10 Fr Blake drain is placed in the neck.
- The neck is closed in layers.
- The flap donor site is closed.

TECH FIG 3 • A. Inset flap demonstrating bulk of the flap (rounded appearance) intraorally. This bulk is necessary to propel food to the back of the mouth. **B.** Muscle inset in the floor of mouth to contain leaks. Microanastomosis is also shown.

PEARLS AND PITFALLS

Patient education and planning

- Patients requiring total glossectomy are at high risk for complications given that they are nutritionally compromised, they have advanced malignancies, they often smoke, and many have had prior surgery or radiation.

Surgical planning

- A successful reconstruction is most often achieved during the primary operation. It is significantly more difficult to achieve a successful reconstruction after a flap has necrosed, a fistula has formed, or a dehiscence has occurred.

Flap design

- A variety of flap designs have been proposed to allow various three-dimensional configurations. More complex shaping and folding of flaps may result in a greater risk of ischemia and partial flap loss, especially among smokers.
- Generally, the flap dimensions should be at least 30% larger than the floor of mouth defect for sufficient bulk. If an ALT flap is used and the patient is thin, a portion of the vastus lateralis can be used or the flap

can be partially de-epithelialized and folded upon itself.

POSTOPERATIVE CARE

- The patient is kept sedated and ventilated by tracheostomy overnight.
- Flap monitoring can be performed with clinical exam, handheld Doppler, or implantable Doppler.
- Oral hygiene is started 2 to 3 days postop with Peridex.
- Swallowing function is assessed before attempts at feeding.
- Drains are removed from the neck at 15 mL/d.
- Drains are removed from donor sites at 30 mL/d.

OUTCOMES

- Although most patients are able to verbally communicate with laryngeal preservation, 85% of patients are found to have intelligible speech.^{1,2}
 - In patients who have simultaneous total laryngectomy, about 50% of patients regain the ability to phonate.
 - Only 30% of those patients have intelligible speech. Reconstruction using free tissue transfer has been independently associated with improved speech outcomes when compared to pedicled reconstruction flaps.
- Most patients recover the ability to swallow after reconstruction of a total glossectomy defect.
 - Feeding tube dependence at 1 year postsurgery has been found to be anywhere from 50% to 75%.^{1,2}
 - At least 75% of patients are able to maintain some type of oral intake with one-third of patients able to be feeding tube independent. Flap choice has not been shown to have any effect on swallowing function.
- Maintenance of the flap bulk and volume is important for speech and swallowing (**FIG 1**).

COMPLICATIONS

- Patients are subject to the usual complications that may afflict any patients with locally advanced head and neck cancer.
 - These include pneumonia, deep vein thrombosis (DVT) or pulmonary embolus, and myocardial infarction.
- Wound healing complications are common, especially in smokers or patients with a history of prior radiation therapy.

FIG 1 • Long-term follow-up view demonstrating good height and bulk of the flap. Also note that the flap has re-epithelialized.

- Small fistulas may be managed conservatively with local care.
- Larger fistulas or those near the vascular pedicle may require operative intervention and closure with a secondary pedicle flap (eg, pectoralis or supraclavicular) as appropriate.
- Total flap loss generally requires a second free flap or possibly a pectoralis myocutaneous flap, depending on the etiology of the flap loss.³⁻⁶

44 Reconstruction of Buccal Mucosal Defects

CHAPTER

Imran Ratanshi and Colleen M. McCarthy

DEFINITION

- Carcinoma can involve the buccal mucosa of the oral cavity.
- The treatment of buccal mucosa cancer is typically surgical resection.

ANATOMY

- The buccal mucosa lines the inner aspect of the cheek and the lip.
- Blood supply to the buccal mucosa is derived from buccal branches of the facial artery, superficial temporal artery, and internal maxillary artery.
- Sensory innervation to the buccal mucosa is provided by the trigeminal nerve.
- Anatomic borders (**FIG 1A**)
 - Superiorly border—attachments to the maxillary alveoli
 - Inferior border—attachments to the mandibular alveoli
 - Anterior border—lateral lip commissure
 - Posterior border—pterygomandibular raphe
- Relevant layers of the cheek from external to internal (**FIG 1B**)
 - Skin
 - Subcutaneous fat
 - Superficial musculoaponeurotic system (SMAS)/platysma
 - Parotid fascia/capsule
 - Parotid gland
 - Parotidomasseteric fascia
 - Masseter muscle
 - Buccal fat pad (within buccal space)
 - Buccinator
 - Buccal mucosa

■ There are three important spaces in the buccal region. These are potential sites for fluid collection, infection, or tumor spread.

■ Buccal space

- Anterior border—oral commissure
- Posterior border—anterior border of masseter
- Superior border—zygomatic process of maxilla, zygomaticus muscles
- Inferior border—depressor anguli oris and attachment of deep fascia to mandible
- Medial border—buccinator muscle (space is superficial to the muscle)
- Lateral border—platysma, subcutaneous tissue, skin

■ Pterygomandibular space

- Anterior border—posterior border of buccal space (anterior border of masseter)
- Posterior border—parotid gland
- Superior border—lateral pterygoid muscle
- Inferior border—inferior border of mandible (lingual surface)

FIG 1 • A. Surface anatomy of the intraoral cheek surface. **B.** Anatomic layers of the cheek illustrated from external to internal. SMAS, superficial musculoaponeurotic system.

- Lateral border—ascending ramus of mandible (space is deep to mandible)
- Medial border—medial pterygoid muscle (space is superficial to this muscle)
- Masseteric (or submasseteric) space
 - Anterior border—anterior margin of masseter
 - Posterior border—parotid gland
 - Superior border—zygomatic arch
 - Inferior border—mandible
 - Lateral border—masseter
 - Medial border—lateral surface of mandibular ramus
- The buccal fat pad (of Bichat) occupies the buccal space. Contents of the buccal fat pad include
 - Motor buccal nerve
 - Sensory buccal nerve (V3)
 - Facial artery and vein
 - Buccal branch of maxillary artery
 - Terminal buccal branches of facial nerve
 - Parotid (Stensen) duct

PATHOGENESIS

- Buccal cancer originates in the mucosal lining of the cheeks inside the mouth.
- Squamous cell carcinoma is the most common type of pathology.
- No single risk factor causes buccal cancer.
- Risk factors for buccal cancer include a history of:
 - Premalignant conditions¹
 - Oral lichen planus and leukoplakia are common premalignant lesions.
 - Malignant conditions
 - Previous aerodigestive cancer
 - Modifiable risk factors^{1,2}
 - Tobacco (particularly chewing tobacco)
 - Alcohol abuse
 - Betel nut [or areca nut] (common in a South Asian chewed delicacy called “paan”)
 - Poor nutrition
 - Poor dentition

- Oral denture wear
- Viruses: HPV-16, HPV-18, HPV-31, HPV-33, and HPV-35; HHV-4 and HHV-8; HIV; EBV¹

PATIENT HISTORY AND PHYSICAL FINDINGS

- Risk factors for buccal cancer should be identified, particularly smoking status. In a patient who is an active smoker, the risk of partial or complete flap loss is greater.
- A history of any prior surgeries or vascular line placement may limit the use of specific reconstructive options.
 - For example, a prior neck dissection may preclude the use of the facial artery musculomucosal (FAMM) flap if the facial artery has been previously ligated.
 - If level 1 (submental) nodes have been previously resected, use of the submental island flap or platysmal island flap is contraindicated.
 - Placement of a radial artery line for invasive blood pressure monitoring is a relative contraindication for use of a radial forearm free flap.
- History and clinical findings of prior irradiation may also be a relative contraindication to a locoregional flap reconstruction, depending on the condition of the tissues.
- A handheld pencil Doppler or duplex ultrasound can be used in the preoperative setting and/or in the operating room to determine the location of arterial perforating vessels.

SURGICAL MANAGEMENT

Preoperative Planning

- Potential donor sites must be considered preoperatively.
- Discussion with the resecting surgeon is helpful to estimate the defect size and potential for close or positive margins. If positive margins are anticipated, other nonsurgical treatment strategies should be explored.
- Need for adjuvant radiation therapy should influence the reconstructive modality.
- It is imperative that patency of the ulnar artery is confirmed with an Allen test in the preoperative period. Use of a bedside pulse oximeter can be a useful adjunct to objectively identify collateral flow in this setting.
- Intravenous and intra-arterial lines must also be avoided in the ipsilateral upper forearm if a radial forearm free flap is to be harvested.

Positioning

- The patient is placed in a supine position with neck in slight extension.
- General anesthesia with nasotracheal intubation will typically be employed.
- Tumor ablation will proceed by the ablative surgeon.
- The reconstructive surgeon may undertake simultaneous harvest of a microvascular flap if the surgical teams are certain that a free tissue transfer is indicated. Partial elevation of a flap may be employed, including pedicle dissection, and may be performed to optimize efficiency.

Approach

- The pliable nature of buccal mucosa allows for full mandible excursion. Therefore, primary closure of small to moderate-sized defects can lead to soft tissue restriction, ultimately resulting in trismus.
- Superficial mucosa-only defects can be reconstructed with a split-thickness skin graft or palatal graft.
- Alternatively, acellular dermis may be used in this setting and can serve as a scaffolding in which vascular ingrowth can occur with minimal scar contraction.
- Flap reconstruction may be indicated in circumstances where more bulk is desired than can be achieved with skin or dermal grafting alone.
- Many local and locoregional flap options have been described. Workhorse flaps utilized in restoring buccal mucosal lining include
 - Pedicled flap options:
 - Buccal fat transposition flap—for small buccal defects
 - Facial artery myomucosal flap—small to moderate-sized buccal defects that involve the alveoli and/or lips
 - Submental artery island flap—moderate-sized buccal defects
 - Platysmal island flap—moderate-sized buccal defects
 - Pectoralis major flap—moderate- to large-sized buccal defects in patients who are poor candidates for free flap reconstruction or in salvage cases
 - Microvascular free flap options—offer additional tissue bulk and the ability to contour donor tissue to fit a defect without restriction
 - Radial forearm fasciocutaneous flap
 - Thin, pliable soft tissue
 - Consistent blood supply with long vascular pedicle
 - Donor-site morbidity includes tendon exposure, injury to the dorsal radial

sensory nerve branch, and inferior appearance.

- Anterolateral thigh fasciocutaneous flap
 - Can often close donor site primarily
 - Best used in very thin patients or those in whom a radial forearm flap is not an option
 - Can be performed as adipofascial flap if more bulky donor site

TECHNIQUES

■ Autogenous Grafts

- For mucosa-only defects, very small defects may be repaired with primary closure. Small defects may be repaired with palatal mucosal grafts. For moderate-sized defects, a split-thickness skin graft can be employed to resurface the intraoral buccal lining.
- Skin grafts should be fenestrated to prevent accumulation of serous fluid and fixed with resorbable suture (eg, cat gut).³
- A tie-over bolster dressing using petroleum-impregnated gauze and nonresorbable suture (eg, silk) should be used to minimize shear and prevent saliva from entering below the skin graft surface.⁴ The bolster can also be tied extraorally.³
- A bite block may be considered if there is concern about dislodging the bolster dressing.
- Grafts should not be considered in the setting of anticipated radiation.

■ Acellular Dermal Matrix

- Human acellular dermal matrix (ADM) is a biomaterial derived from cadaveric skin that has been processed to remove cells and immunogenic antigens.
- ADM may be used in a similar manner to a skin graft.
- The ADM is sutured into place and a bolster applied similar to a skin graft.
- The bolster should be kept in place for 3 to 7 days.⁵
- Failure presents as a pale graft that easily sloughs from its wound base.

- Mild contraction can occur that is maximal at 3 to 5 weeks.⁵

■ Buccal Fat Pad Flap

- The body of the buccal fat pad is centrally located over the parotid duct.
- The blood supply includes branches of the facial artery, internal maxillary artery, superficial temporal artery, and maxillary artery.
- The buccal fat pad can be mobilized to resurface a defect.
- Suitable for moderate-sized defects up to 5 cm. Cheek depression can occur in larger defects.⁶
- The flap can be mobilized through a 1-cm horizontal incision in the molar region, 5 mm above the second molar, and halfway between the Stensen duct and the upper gingivobuccal sulcus.
- An incision is then made in the buccinator muscle, and the capsule surrounding the fat pad is entered bluntly so as not to disrupt the buccal branches of the facial artery.
- Gentle extraoral pressure will help deliver the fat pad.
- The fat pad is mobilized and fixated into the adjacent defect with resorbable suture.
- The flap will be resurfaced by via re-epithelialization over 4 to 6 weeks.
- A bite block or splint should be considered for 12 to 14 days to avoid chewing through the pedicle or causing trauma to the flap.^{7,8}

■ Submental Island Flap

- The submental artery island flap is an axial fasciocutaneous flap.
- The vascular pedicle is based off the submental artery and vein and has a length of up to 5 cm. The submental artery takes origin from the facial artery 5 cm anterior the mandibular angle. It runs a tortuous course and supplies the submandibular gland and level 1 (submandibular) lymph nodes. The submental artery runs deep to the digastric muscle in 70% of cases. Therefore, the digastric muscle may be included in the flap.⁹
- The skin paddle of the submental artery extends from one angle of the mandible to the other. A pinch test determines the flap width. The flap comprises the skin, subcutaneous fat, platysma muscle, submental fat, and

lymph nodes.

- A handheld Doppler is used to identify cutaneous perforators just posterior to the mandibular arch and adjacent to the anterior belly of digastric.
- The upper border of the flap is drawn approximately one to two fingerbreadths below the lower border of the mandible to protect the marginal mandibular nerve and to reduce the risk of visible scar.^{8,10}
- The skin markings are incised down to and through the platysma muscle, taking care to preserve the common or anterior facial veins and the marginal mandibular nerve deep to platysma.
- Starting on the contralateral side to the pedicle, a subplatysmal dissection is then performed from lateral to medial.
- Next, the ipsilateral side is elevated. The skin is incised down to and through the platysma muscle similar to the contralateral side. The submental arteries are identified deep to the submandibular gland superiorly and are skeletonized with the subplatysmal skin island. Use of a handheld Doppler at this stage can be useful to identify and protect the pedicle.
- The anterior digastric muscle overlying the pedicle is harvested and included with the flap to protect the blood supply (**TECH FIG 1**).
- A tunnel is then made through the ipsilateral mylohyoid muscle to facilitate transfer into the oral cavity. A strip of mylohyoid muscle may be included with the pedicle to improve ease of transfer.
- The neck is then primarily closed. This can be aided by slight neck flexion.
- Tension on the pedicle may be minimized in the early postoperative period by turning the head toward the pedicle.

TECH FIG 1 • Elevation of the submental island flap.

■ Platysmal Myocutaneous Island Flap

- The platysma is a paired Mathes and Nahai type II muscle that originates from the superficial fascia of pectoralis major and inserts over the angle of the mouth and caudal cheek.
- The dominant pedicle is the submental artery and venae comitantes. The minor blood supply is a branch of the suprasternal artery, which in turn is a branch of the suprascapular artery and vein.
- The skin island in a platysmal flap should be designed in the hairless region of the neck overlying the insertion of the sternocleidomastoid. A pinch test can be performed to estimate the flap width, but it should not exceed more than 5×7 cm.
- Flap dissection should be undertaken prior to tumor extirpation and neck dissection to avoid injury to the pedicle.
- The distal border of the flap is incised to and through the platysma muscle.
- The proximal border of the flap is incised through the skin only, preserving platysma muscle.
- The flap is then elevated from distal to proximal in a subplatysmal plane. Care should be taken to identify the marginal mandibular nerve.

Consideration should also be given to include the anterior belly of digastric muscle.^{8,11}

- The pivot point is about the lower border of the ipsilateral mandible.
- This flap may be at risk for venous congestion from compression over the mandible and can result in flap tip necrosis.

■ FAMM Flap

- The FAMM flap is an axial flap based on the facial artery.
- The course of the artery should be mapped extraorally and intraorally. The facial artery takes origin from the external carotid artery. The location of the facial artery can be identified along the lower border of the mandible, three fingerbreaths from the mandibular angle at the anterior border of the masseter muscle. The artery follows a tortuous course between the buccinator muscles and the muscles of facial expression toward the alar base. It is approximately one-half of an inch lateral to the oral commissure and one-quarter of an inch from the alar base. It continues as the angular artery and travels toward the medial canthus. This can be confirmed using a handheld Doppler.
- The FAMM flap is designed along the course of the facial artery just anterior to the parotid (Stensen) duct and consists of the buccal mucosa, a small amount of buccinator muscle, the facial artery, and a venous plexus (**TECH FIG 2A**). It can be approximately 1.5- to 2-cm wide.
- Both superiorly and inferiorly based flaps can be used depending on the defect location and arc of rotation required.
- To aid in the dissection, stay sutures can be placed above and below the commissure to create a taut buccal mucosa.
- Sharp dissection is used to dissect through the buccinator muscle to identify the artery.
- The artery is ligated distally, and dissection is then carried from distal to proximal to identify the artery near the oral commissure. Attachments of the facial artery to the overlying buccinators can be tenuous and must be kept intact.
- Once the flap is harvested, it is transposed and inset (**TECH FIG 2B**). The donor site may be closed primarily or grafting may be undertaken.¹²

TECH FIG 2 • Elevation (**A**) and transposition (**B**) options for the facial artery myomucosal (FAMM) flap.

■ Pectoralis Major Myocutaneous Flap

- The pectoralis major flap is a useful flap in patients with large buccal defects who have medical comorbidities that preclude free flap reconstruction or in salvage circumstances.¹³
- The pectoralis major is a Mathes and Nahai type V muscle whose dominant pedicle is the thoracoacromial artery and venae comitantes. Minor pedicles arise from the lateral thoracic artery and anterior perforators from the internal mammary artery between the second and fifth ribs. The sternocostal portion originates from the anterior chest wall from the second to sixth ribs.
- The pivot point is just below the clavicle. The surface landmark of the thoracoacromial pedicle the intersection of a line from the acromion process to the xiphoid notch, and a plumb line from the midclavicle. The pedicle can be found within a 2-cm radius of this point.
- Using reverse planning, a vertical or horizontal skin paddle can be designed

centered on the pectoralis major.

- The lateral flap is incised to anterior pectoralis muscle fascia. Skin and soft tissue lateral to the flap are then widely undermined.
- Next, the medial flap is incised to pectoralis muscle fascia, providing complete exposure of the muscle.
- The muscle is then elevated from distal to proximal, ligating the intercostal and lateral thoracic perforators.
- If an ipsilateral deltopectoral flap may be required, preservation of the second and third internal mammary perforators should be considered.
- During the lateral dissection, the pectoralis major is disinserted to facilitate mobilization. Ligation of the lateral pectoral nerve can also be considered for further reach.
- A subcutaneous tunnel overlying the clavicle is then developed to facilitate flap transfer toward the neck.
 - The medial half of the clavicle can also be divided to provide additional length and minimize compression on the venae comitantes.
- This flap is limited by additional bulk and may not be suitable for obese patients.
- A bulge will be observable on the ipsilateral neck where the flap has been turned over.

■ Radial Forearm Fasciocutaneous Free Flap

- The flap is harvested from the nondominant forearm (**TECH FIG 3**).
 - The course of the radial artery and superficial veins, including the cephalic vein, is marked.
 - Proximal venous compression can aid in identifying the superficial venous system.
 - The approximate course of the medial and lateral antebrachial cutaneous nerves can also be marked.
- The radial forearm flap is usually centered so that the midpoint of the flap follows a line halfway between the radial artery and the cephalic vein.
- The limb is exsanguinated and tourniquet is inflated.
- The distal flap margin is incised.
- Blunt dissection is used to identify three main structures:
 - Distal branches of the superficial radial nerve

- The radial artery and venae comitantes between the flexor carpi radialis and brachioradialis tendons
- The cephalic vein on the distal radial edge of the flap
- The radial artery, venae comitantes, and cephalic vein are ligated distally.
 - When results of an Allen test are in doubt, an Acland clamp can be placed on the radial artery to definitively assess hand perfusion prior to ligating the radial artery.
- An incision is made on the ulnar flap margin through the skin and fascia.
- Flap elevation proceeds from an ulnar to a radial direction deep to the volar antebrachial fascia, carefully protecting the paratenon overlying the wrist flexor tendons.
- The flexor carpi radialis muscle is identified, as is the lateral intermuscular septum on the lateral aspect of the muscle. Traction of the muscle in an ulnar direction will reveal the radial artery and its venae comitantes.
- An incision is made along the radial margin of the flap through the skin and underlying volar antebrachial fascia, and the flap is elevated from radial to ulnar, again preserving paratenon overlying the wrist flexor tendons, until the brachioradialis tendon is identified. Care must be taken to preserve the superficial sensory branches of the radial nerve.
- As dissection proceeds from the radial margin of the flap, the fascia is lifted off of the brachioradialis. The further proximal the dissection, the more the brachioradialis muscle conceals the artery beneath its volar medial border.
- The proximal flap margin is then incised, avoiding injury to the cephalic and basilic veins, as well as to the medial and lateral antebrachial cutaneous nerves.
- The lateral intermuscular septum and associated radial artery and venae comitantes and perforators are then elevated in a distal to a proximal direction. Deep branches to the volar surface of the distal radius and to adjacent muscle bellies are ligated.
- At the approximate junction of the middle and distal thirds of the arm, the superficial branch of the radial nerve penetrates the deep fascia to course superficial to this fascia. From this point of penetration distally, the deep fascia is incised longitudinally, freeing the nerve.
- A longitudinal incision proximally toward the antecubital fossa allows elevation of the proximal radial artery and any subcutaneous veins all the way to the bifurcation of the brachial artery as is necessary. A Weitlaner or

other retractor is useful to expose the pedicle deep to the brachioradialis and flexor carpi radialis muscle bellies. The proximal length of the cephalic vein can be dissected to be as long as required.

- The tourniquet is deflated, and immediate reperfusion of the flap and of the hand is revealed.
- A split-thickness skin graft is needed to close the donor site. The wrist should be immobilized for 2 weeks to avoid graft shear from the underlying wrist flexors.

TECH FIG 3 • Anatomic structures encountered during elevation of the radial forearm flap.

■ Anterolateral Thigh Fasciocutaneous Flap

- The anterolateral thigh flap is useful for moderate- to large-sized buccal defects in circumstances where the radial forearm is not an available donor

site (**TECH FIG 4A,B**).¹⁴

- A line is drawn between the anterior superior iliac spine to the superolateral border of the patella. This line represents the muscular septum between the rectus femoris and the vastus lateralis muscles (**TECH FIG 4C**).
- The cutaneous vessels are mapped by a Doppler probe centered over the midpoint of this line. Most skin perforators are located within a circle of 3-cm radius centered at this midpoint. The flap is centered over the location of these vessels, and its long axis is designed parallel to that of the thigh.
- Additional perforators can often be found 5 cm distal and 5 cm proximal to this point. If perforators cannot be readily identified, a Duplex ultrasound is useful in definitively identifying perforators. If none can be found, the opposite thigh should be considered.
- An incision is made along the distal 10 to 15 cm of the medial aspect of the flap down to and through the deep fascia on to the rectus femoris muscle belly.
- The rectus femoris muscle is identified based on its bipennate muscle fibers and a flat, stout tendon spanning its entire undersurface. A fat plane exists superficial to the lateral intermuscular septum between the rectus femoris and vastus lateralis.
- Once the septum is identified, the remaining medial skin and fascia incision is completed from distal to proximal.
- The rectus femoris muscle is retracted medially to expose the entire septum.
- The septocutaneous vessel can be clearly observed. An appropriate perforator can be selected. A pure septocutaneous course is less common. In most cases, the perforator follows a varied intramuscular course and typically gives off many small branches to the vastus lateralis muscle from the lateral and posterior sides of the vessel.

TECH FIG 4 • Use of an ALT free flap to reconstruct a full-thickness buccal defect from resection of an invasive squamous cell carcinoma. **A.** Planned resection with margin. **B.** Final defect. **C.** Surface landmarks for perforators and perforator anatomy for anterolateral thigh flap based on the lateral circumflex femoral system. **D.** Elevated ALT flap with vascular pedicle marked in ink on one side to identify twisting. **E.** The flap was folded to provide both intraoral lining and external skin. The interposing segment connecting the two surfaces was de-epithelialized. **F.** Final inset showing external skin paddle (internal paddle not shown).

- The superficial (anterior) course of the perforator is then exposed by dividing the overlying muscle, and the perforator is traced back to the main descending branch of the lateral circumflex femoral artery. The perforator can then be freed on its lateral, medial, and deep surfaces to free it completely to its origin.
- Once the perforator is freed, the lateral skin marking is incised down to and through the deep fascia.
 - The flap is elevated from a distal to proximal and lateral to medial direction, with care being taken to preserve the perforator (**TECH FIG 4D**).
- Once the flap is harvested, it is transposed and inset (**TECH FIG 4E,F**).
- Primary closure of the donor site can often be achieved. For larger skin paddles, a split-thickness skin graft may be required.
- In circumstances in which there is extensive subcutaneous tissue in the thigh, an adipofascial flap may be considered. This allows better tailoring to fit the defect thickness. The fascial surface that does not stretch is allowed to remucosalize.¹⁵ Therefore, it must be fitted to size or trismus will result.

■ Cutaneous Paddles of Chimeric Flaps

- Loss of buccal and additional oral cavity mucosa may be part of a composite defect involving bone, floor of mouth, and tongue.
- Chimeric flap designs can offer a skin cover for mucosal lining defects in conjunction with bone for segmental defects or muscle for dead space obliteration if required.
- Buccal resurfacing can be achieved using skin paddles of chimeric flaps.
 - Common examples include fibula osteocutaneous flap, scapula osteocutaneous flap, anterolateral thigh myocutaneous flap, and iliac crest osteocutaneous flap.

PEARLS AND PITFALLS

Complication

Iatrogenic injury to the

Pearls for Management

- When harvesting a submental island flap, the patient should not be paralyzed until after the mandibular branch of the facial nerve

marginal mandibular nerve during submental flap harvest	is identified.
Poor skin graft take	■ A bolster dressing of Xeroform and silk sutures may be applied to protect the skin graft from sheer and saliva. This should be maintained for 7 days.
Wound dehiscence	■ When inseting the flap, care should be taken to ensure a watertight closure. Horizontal mattress sutures can be helpful. However, sutures should not be overtight so as not to cause flap tip necrosis and poor healing. Where watertight closure is not possible, consideration of placing additional muscle to obliterate the dead space between the cheek and neck.
Fistula tract formation	■ Acute fistulas are best managed with regular irrigation and through-and-through intraoral and extraoral packing. Intraoral packing with Vaseline-impregnated gauze or Xeroform helps to form a plug to minimize saliva entry into the neck. Extraoral packing with saline-soaked or dry gauze helps to remove necrotic or infected debris.
Vascular compromise	■ Care should be taken to avoid excess pressure on the neck at the site of a vascular pedicle and/or anastomosis.

POSTOPERATIVE CARE

- A nasogastric tube or similar device should be employed until graft or flap take is established and intraoral wounds are sealed, usually around postoperative day 7.
- Pressure avoidance at the microvascular site is essential to reduce the risk of venous thrombosis, particularly if the external jugular system is used for venous anastomosis. If utilized, tracheostomy ties should not cause any neck compression whatsoever (while equally preventing the tracheostomy from dislodging).
- Securing the tracheostomy with sutures should be considered in circumstances in which this is not possible.
- Position restrictions that prevent a patient from turning toward the side of venous anastomosis can reduce the risk of twisting the venous pedicle and subsequent thrombosis.

- Routine monitoring of microvascular free tissue transfer should include an evaluation of both arterial and venous systems.
- For flaps whose skin paddles are difficult to visualize, a Cook-Swartz Doppler probe or equivalent device should be considered.

OUTCOMES

- The buccal region is important in speech, oral preparatory phase of swallowing, oral competence, and generating suction.¹⁶
- Loss of function results more from tumor extirpation, reconstruction, and radiation than the inciting tumor.
- If the donor tissue chosen appropriately meets the defect requirements, excellent functional outcomes can be achieved.
- Wound dehiscence can lead to fistula and abscess formation. This can delay adjuvant treatments such as radiation or chemotherapy. Therefore, efforts should be undertaken to avoid this complication where possible.

COMPLICATIONS

- Partial or complete graft loss
- Partial or complete flap loss
- Delayed wound healing
- Motor or sensory nerve injury
- Fistula formation
- Abscess formation
- Scar contracture
- Trismus
- Altered speech
- Loss of oral competence

45 Jejunum Flap for Pharyngeal Reconstruction

CHAPTER

Farooq Shahzad and Babak J. Mehrara

DEFINITION

- The free jejunal flap is a workhorse for reconstruction of the hypopharynx and cervical esophagus.
- A flap of up to 20 cm can be harvested on a single jejunal vessel and its vascular arcade. This length limits the use of this flap for reconstruction of subtotal or total esophageal defects.
- For subtotal or total esophageal reconstruction, pedicled colon or gastric pull-up procedures are more appropriate in most cases.
 - However, both of these options have limited reach cephalad and may not extend all the way to the pharynx. In this situation, they can be combined with a free jejunal flap for the pharyngeal and cervical esophageal part of the reconstruction.
- Alternatively, total esophageal reconstruction can also be performed with a pedicled jejunal flap (pedicled in the abdominal donor site) with supercharging the distal flap arcade in the neck or chest.¹

ANATOMY

- The jejunum is the second part of the small intestine. It starts from the ligament of Treitz and extends to the ileum.
 - The lumen of the jejunum contains circular mucosal folds called plicae circulares.
 - These folds slow down the passage of food and increase the surface area for absorption.
 - They decrease in size and number distally along the small bowel.
- The blood supply of the small bowel is via the superior mesenteric artery. It

gives rise to multiple jejunal and ileal branches (**FIG 1**).

- These branches divide and form vascular loops called arcades.
- These arcades further divide to form secondary and tertiary arcades.
- The terminal vessels that supply the small bowel area are called the vasa recta.
- The veins accompany the arteries.
- A jejunal flap can be based on any jejunal artery and its accompanying vascular arcade. Free jejunal flaps are typically based on the ileal vascular arcade as defined by the recipient site needs (see below).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and physical exam should identify those patients who are not eligible for the operation.
- Contraindications include chronic intestinal disease (eg, Crohn disease), ascites, and grave medical condition precluding a long operation.

FIG 1 • Anatomy of the jejunum and intestines.

- Relative contraindications include multiple previous abdominal surgeries and limited pulmonary reserve.
- Other donor sites are assessed for potential backup options, including the pectoralis flap, internal mammary artery perforator (IMAP) flap, deltopectoral flap, supraclavicular flap, radial or ulnar forearm flaps, and anterolateral thigh (ALT) flap.
- Patients with thrombotic tendencies should be identified. This includes a history of deep vein thrombosis (DVT) or miscarriages or family history of thromboembolism.
- A hypercoagulability workup and hematology consult can be obtained if necessary.

IMAGING

- In general, no specific imaging is needed.
- A mesenteric angiogram can be performed to evaluate the patency of the vascular pedicle in patients suspected of having atherosclerotic occlusive disease. However, this is rarely done as the superior mesenteric artery is typically spared from atherosclerosis.

SURGICAL MANAGEMENT

- Jejunal free flap is most commonly used for circumferential defects of the cervical esophagus.
- It can also be used to patch smaller defects or repair incomplete defects, but in these situations, we prefer the radial forearm or ALT flaps.
- The ALT free flap is also a good option for circumferential pharyngoesophageal defects.
- The donor site for this flap usually requires a split-thickness skin graft, however, and is, in our opinion, more morbid than a jejunum flap. In addition, tubing an ALT flap results in an extra suture line (in addition to the proximal and distal pharyngeal anastomosis) requiring more surgical time and potentially increasing the risk of leak.
- As a result, we use this flap as a second-line option when the jejunum cannot be used. However, this idea is heavily debated.
- In patients who are not free flap candidates (medical condition necessitating a short operation or no available recipient neck vessels), regional pedicled flaps

like the pectoralis major myocutaneous flap or supraclavicular flap are more commonly used.

Preoperative Planning

- The plan for resection and neck dissection should be discussed with the ablative head and neck surgeon. This allows for a better understanding of the anticipated surgical defect so that a reconstructive plan can be developed. Furthermore, an informed discussion can be held with the patient, and appropriate consent can be obtained.
- It is also important to discuss the need for preservation of recipient vessels with the ablative surgeon.
- Preoperative bowel preparation can be performed. Often, a simplified bowel prep with clear liquid diet for 24 hours and a bottle of magnesium citrate the day before surgery is all that is necessary.

Positioning

- The patient is placed in the supine position for the duration of the case.
- Perioperative antibiotic prophylaxis is performed. We use cefazolin and metronidazole for head and neck cases.
- Sequential compression devices are used for DVT prophylaxis. Underbody warming device is used to prevent hypothermia during the case.
- The face and neck are prepped with an iodine-based solution.
 - The chest and abdomen are prepped with a chlorhexidine-based or iodine-based solution.
 - The entire field is draped as one for convenience.
 - The chest can be covered with a drape or towel to prevent heat loss.

Approach

- The jejunal flap can be harvested via an open or a laparoscopic approach.
- Open harvest of the jejunal flap is our preferred method. It is performed via a midline epigastric incision. Generally, we make an 8-cm incision above the umbilicus.
 - This technique is technically easier and expeditious and allows direct visualization of the flap and pedicle.
 - Moreover, the pedicle can be separated in situ prior to flap harvest, which is easier to perform than after pedicle division and cuts down on ischemia time.
- Laparoscopic-assisted harvest of the jejunal flap is performed via multiple

small laparoscopic incisions.² It requires expertise in minimally invasive techniques.

- This usually means that the assistance of a general surgeon is required for flap harvest.
- The advantage is decreased abdominal wall morbidity.
- The jejunum tolerates ischemia for approximately 2 to 2.5 hours. Thus, meticulous planning and expeditious execution are critical for a successful outcome.
- Hypothermia increases the ischemic tolerance of jejunal flaps, and some experts have described improved ischemic tolerance with cooling the flaps to 5°C,³ 6°C to 12°C,⁴ and 10°C.⁵ This is generally not necessary, as ischemia times are kept less than 2 hours if the recipient vessels are prepared and the team is ready to perform microsurgical anastomosis when the flap is harvested. In fact, some suggest that 2 hours of eutermic ischemia time is beneficial for postoperative outcomes as this approach may decrease mucous production.⁶

TECHNIQUES

■ Free Jejunum Reconstruction After Laryngopharyngectomy

Preparation of Recipient Area

- The extirpative defect is analyzed.
 - The length of the hypopharyngeal/esophageal defect is measured, and a determination is made whether it is amenable to reconstruction with free jejunal flap (**TECH FIG 1**).
 - If not, an alternate method of reconstruction is chosen.
- Recipient vessels in the neck are dissected and prepared.
 - The recipient artery and vein should be located close to each other because the donor vessels in a jejunal flap cannot be very widely separated.
 - The recipient artery is usually the superior thyroid, facial, or lingual artery.
 - The recipient vein is usually a branch of the internal jugular vein, the main trunk of the internal jugular vein (end to side), or the external jugular vein.

- However, any suitable artery or vein situated close together may be used.
- It is important to dissect the recipient vessels first (ie, prior to flap dissection) because the location of the vessels in relation to the defect determines flap design (see below).
- If there is pedicle bleeding or other problems during flap harvest, the flap can be immediately harvested, inset, and revascularized without additional increases in ischemia time.

TECH FIG 1 • Defect after laryngopharyngectomy.
Note wide skin excision and resection of the pharynx.

■ Jejunal Flap Harvest

- A midline abdominal incision is made, from the xiphoid to above the umbilicus. The deep fascia and peritoneum are opened up to get access to the celiac cavity.
- The greater omentum and transverse colon are retracted cephalad.
 - The small bowel is run back till the ligament of Treitz is identified. From here, the small bowel is run for approximately 30 to 40 cm distally.
 - In this location, a suitable segment of jejunum is chosen for the flap. This

is because the vascular arcades are longest in this area, thus allowing longer pedicle length. Bowel reanastomosis is also easy here. Moreover, in the unfortunate event of flap pedicle thrombosis, another segment of bowel can be harvested more distally.

- The bowel is transilluminated to identify a suitable vascular arcade to base the flap on (**TECH FIG 2A**).
- Dimming the operating room lights and then shining the overhead lights or the headlight along an angle is used to illuminate the flap pedicle against a dark background.
- In choosing an optimal segment of bowel, important considerations are the length of bowel needed and the position of the recipient vessels in the neck in relation to the proximal jejunal anastomosis with the pharynx (**TECH FIG 2B,C**).
- The distance along a diagonal line from the proximal cervical defect to the position of the recipient vessels in the neck is measured and is used to design the flap with a vascular pattern that will minimize kinking, stretching, or compression of the anastomosis.
- The bowel and the accompanying fan-shaped piece of mesentery to be harvested are marked with a marker or methylene blue.
- The proximal bowel end is marked with a stitch to maintain orientation.
- The mesentery is ligated as a fan shape with the apex toward the pedicle.
- Dissection is begun by opening the mesentery adjacent to the bowel ends.
- A Penrose drain is placed through this opening on each side around the bowel for retraction.
